tools, Aquila [31] and p4v [30], to debug a DP generator with equal bug coverage. This means that both *Firebolt* and verification tools take thousands of intents generated by *Firebolt* as input. As shown in Table 4, *Firebolt* requires $O(100)$ of per-symbol LoC to automatically generate the specifications of all intents. In comparison, verification tools require $O(100)$ to $O(1K)$ LoC to convert one intent. Converting all intents means $O(100K)$ to $O(1M)$ LoC. Under equal bug coverage, *Firebolt* consumes merely 0.1% to 0.01% manual efforts compared to existing tools. Moreover, human-written specifications can be faulty, which further reflects the scalability of *Firebolt*.

Scaling to larger test case. We evaluate the scalability of *Firebolt* when verifying larger P4 programs with more table entries. We use several open-source or vendor-supplied P4 programs instead of the small programs generated by *Firebolt*.

First, we measure the time required by *Firebolt* to verify P4 programs of different sizes. For each program, we manually write <3 entries for each table, and also write the corresponding specifications for verification. As shown in Figure 9(a), *Firebolt* requires more time for verification as the complexity of the P4 program increases. Nevertheless, even the most complex switch.p4 can be verified in 8 minutes.

Next, we compare the verification time when installing different numbers of table entries to the same P4 program fabric.p4. As shown in Figure 9(b), the number of table entries has a larger impact on the verification time than the size of P4 program. When the number of entries does not exceed 1500, *Firebolt* can complete the verification in <30 minutes. When the number of entries exceeds 2000, *Firebolt* takes >100 minutes for verification. The increase is not linear because the table entries are converted into if-then-else branches, resulting in an exponential increase in the size of the generated Z3 formulas. This non-linear scalability of verification time with table entries has also been recognized in other verification works [31] and solved using encoding optimizations. Currently, *Firebolt* by design generates small test cases without losing bug coverage using intent space pruning. For upcoming generators, we may encounter larger intents, programs, and table entries that become more time-consuming

to verify. In that case, *Firebolt* can refer to the optimization techniques in existing verification tools [30, 31] to accelerate the verification of individual intent-program pairs.

7 Discussion

Human effort required by *Firebolt*. *Firebolt* requires three inputs, including grammar, semantic constraints, and per-symbol specification to debug a DP generator. First, the grammar should already be provided by the designers of DP generators [14, 16, 21–23] so that the DP generator can be used correctly by others. Second, accurate semantic constraints also help to better use the DP generator. We summarize the semantic constraints of three advanced DP generators in Appendix A. They all have <20 semantic constraints that can be classified into four types, *i.e.*, banned variable redefinition, necessary variable definition, illegal variable reference, and special ones. The former three types account for the majority of the constraints and are closely related to variable definitions and references. Semantic constraints can shrink the intent space, and missing some semantic constraints will not affect the bug coverage but merely produce more intents. Third, *Firebolt* requires manually writing per-symbol specification. However, compared with existing tools, *Firebolt* saves significant human efforts by automatically composing per-symbol specifications into intent specifications.

Cross-platform generality of *Firebolt*. The formalization phase of *Firebolt* considers extern behaviors because they are critical for the correctness of DP generators. However, the semantics of extern behaviors are target-specific. Currently, *Firebolt* supports two common extern implementations including stateful memory and hash calculation. Since externs can be taken as arithmetic operations on some variables (*e.g.*, temporal variable, metadata field, and packet header), they can always be converted into logical Z3 formulas. As a future work, we would like to extend *Firebolt* to support user-defined extern semantics to improve cross-platform generality.

8 Related Work

Data plane generator. To simplify DP programming, a growing body of research proposes data plane generators which convert high-level intents into platform-specific DP programs. DP generators provide primitives to specify developer intents in different domains, *e.g.*, query primitives for monitoring tasks [15–20], measurement and control primitives to specify security policies [21, 22] and routing policies [23], and some other intent languages for their own purposes [14, 24–27]. DP generators greatly relieve the burden of DP programming, but their own correctness is not guaranteed. In this paper, we design a blackbox-based testing system to debug them.

Data plane program verifier. Several efforts have been proposed to verify DP programs. P4-assert [28] and Vera [29] translate P4 programs into other language models (SEFL

and C) and rely on existing symbolic execution framework (SymNet [46] and Klee [47]) to analyze the behavior of the resulting programs. p4v [30] and Aquila [31] use Dijkstra’s classic verification approach by formalizing the P4 program in Guarded Command Language (GCL) and using the Z3 theorem prover [35] to check whether the specifications hold. Some other tools, such as bf4 [32] and P6 [34], utilize various techniques such as static verification, code changes and runtime checking to ensure that the deployed P4 program is bug-free. However, using these tools to debug DP generators cannot cover all generator bugs and requires massive manual efforts to verify each possible intent-program pair. Different from all of them, *Firebolt* can automatically generate representative intents as test cases for high coverage and automatically produce intent specifications for high scalability.

Testing in networking. Testing is a popular technique to find bugs in network systems by generating and running many test cases. Metha [48] tests network verification tools by generating network configurations as test cases and comparing the tool’s output with that of the actual router. p4pktgen [49] tests P4 programs by generating test cases using symbolic execution. Gauntlet [42] and P4Fuzz [50] both test the P4 compiler by generating random P4 programs. If the intermediate representation (IR) of the compiler is accessible, Gauntlet compares the transformed programs after different compiler passes, otherwise it generates packets to test the behavior of the P4 program to debug the compiler. P4Fuzz compares the output of different compilers to find potential bugs. *Firebolt* also uses generation-based testing to debug DP generators. However, unlike existing work to test specific targets, *Firebolt* needs to handle a variety of DP generators. *Firebolt* adopts a syntax-guided approach to generate test cases and designs generic methods to verify the correctness of each test case.

9 Conclusion

This paper presents *Firebolt*, a blackbox testing tool designed to debug DP generators. We propose syntax-guided intent generation with semantic constraint injection and intent space pruning techniques, and program verification with automatic intent and program formalization. By evaluating three popular open-source DP generators, we show the high bug coverage and scalability of *Firebolt* compared to existing solutions.

This work does not raise any ethical issues.

Appendix A Semantic Constraints of Advanced DP Program Generators

Table 5 lists the identified semantic constraints for Marple [16], Sonata [17], and Poise [21]. The semantic constraints can be classified into four categories, *i.e.*, banned variable redefinition, necessary variable definition, illegal variable reference to generate *compilable* intents, and other special constraints to generate *complete* intents. For each category, we give an example of how the constraint can be expressed with the formal *if-then* expressions in §4.2.

Table 5: Summary of semantic constraints of Marple [16], Sonata [17], and Poise [21].

| Constraints | | Description | Type | Expression |
|--|--|--|--|---|
| Marple | Banned Variable Redefinition (3) | #1: Each query has a stream name, which cannot be repeatedly defined. | Exclusion | #1 as an example: $if \exists r_1 \text{ on } n_1, \nexists r_2 \text{ on } n_2, n_1 \leftrightarrow n_2$ $\langle n_1 \rangle: *, \langle prog \rangle \langle streamStmt \rangle \langle streamName \rangle, *$ $\langle r_1 \rangle: \langle streamName \rangle \rightarrow *$ $\langle n_2 \rangle: *, \langle prog \rangle \langle streamStmt \rangle \langle streamName \rangle, *$ $\langle r_2 \rangle: \langle r_1 \rangle$ |
| | | #2: Each aggregation function has a function name, which cannot be repeatedly defined. | | |
| | | #3: A aggregation function may define multiple aggregation states. The aggregation state names cannot be repeatedly defined. | | |
| | Necessary Variable Definition (8) | #4~7: Each query (<i>map/groupby/filter/zip</i>) operates on a stream, which should be either defined or the default input stream T. | Dependency | #4 as an example: $if \exists r_1 \text{ on } n_1, \exists r_2 \text{ on } n_2, n_1 \rightarrow n_2$ $\langle n_1 \rangle: *, \langle prog \rangle \langle streamStmt \rangle \langle streamQuery \rangle \langle map \rangle \langle streamName \rangle, *$ $\langle r_1 \rangle: \langle streamName \rangle \nrightarrow T$ $\langle n_2 \rangle: *, \langle prog \rangle \langle streamStmt \rangle \langle streamName \rangle, *$ $\langle r_2 \rangle: \langle r_1 \rangle$ |
| | | #8: <i>groupby</i> queries take an aggregation function name as input. The function should be defined. | | |
| | | #9: <i>groupby</i> queries may include self-defined variables in the aggregation key. The variables should be defined. | | |
| #10: <i>filter</i> queries may reference self-defined variables in its predicate. The variables should be defined. | | | | |
| Illegal Variable Reference (2) | #11: <i>map</i> queries may reference self-defined variables. The variables should be defined. | Exclusion | #12 as an example: $if \exists r_1 \text{ on } n_1, \nexists r_2 \text{ on } n_2, n_1 \leftrightarrow n_2$ $\langle n_1 \rangle: *, \langle prog \rangle \langle streamStmt \rangle \langle streamQuery \rangle \langle map \rangle \langle map_col \rangle, *$ $\langle r_1 \rangle: \langle map_col \rangle \rightarrow *$ $\langle n_2 \rangle: *, \langle prog \rangle \langle streamStmt \rangle \langle streamQuery \rangle \langle map \rangle \langle map_col \rangle, *$ $\langle r_2 \rangle: \langle r_1 \rangle$ | |
| | #12: <i>map</i> queries assign specified or self-defined variables to computed expressions, where the variables should not be assigned repeatedly. | | | |
| Special Semantic Constraints (1) | #13: <i>zip</i> queries merge fields in <i>different</i> streams. | Dependency | #14 as an example: $if \exists r_1 \text{ on } n_1, \exists r_2 \text{ on } n_2, n_1 \rightarrow n_2$ $\langle n_1 \rangle: *, \langle prog \rangle \langle streamStmt \rangle \langle streamQuery \rangle, *$ $\langle r_1 \rangle: \langle streamQuery \rangle \rightarrow \langle map \rangle$ $\langle n_2 \rangle: *, \langle prog \rangle \langle streamStmt \rangle \langle streamName \rangle, *$ $\langle r_2 \rangle: \langle streamQuery \rangle \rightarrow \langle filter \rangle \langle groupby \rangle \langle zip \rangle$ | |
| #14: An intent should not end with a <i>map</i> query. | | | | |
| Sonata | Special Semantic Constraints (2) | #1: An intent should not end with a <i>map</i> query. | Dependency | #1 as an example: $if \exists r_1 \text{ on } n_1, \exists r_2 \text{ on } n_2, n_1 \leftarrow n_2$ $\langle n_1 \rangle: *, \langle prog \rangle \langle streamQuery \rangle, *$ $\langle r_1 \rangle: \langle streamQuery \rangle \rightarrow \langle map \rangle$ $\langle n_2 \rangle: *, \langle prog \rangle \langle streamQuery \rangle, *$ $\langle r_2 \rangle: \langle streamQuery \rangle \rightarrow \langle filter \rangle \langle reduce \rangle \langle distinct \rangle$ |
| | | #2: <i>reduce</i> queries should follow <i>map</i> queries. | | |
| Poise | Banned Variable Redefinition (2) | #1: Each <i>list</i> has a name, which cannot be repeatedly defined. | Exclusion | Similar to the banned variable redefinition of Marple. |
| | | #2: Each <i>monitor</i> function has a name, which cannot be repeatedly defined. | | |
| | Necessary Variable Definition (2) | #3: Each <i>monitor</i> function references a <i>list</i> , which should be defined. | Dependency | Similar to the necessary variable variable definition of Marple. |
| | | #4: A <i>statement</i> may reference a <i>monitor</i> function, which should be defined. | | |

Investigating Managed Language Runtime Performance

Why JavaScript and Python are 8x and 29x slower than C++, yet Java and Go can be faster?

David Lion^{*†}, Adrian Chiu^{*}, Michael Stumm^{*}, Ding Yuan^{*†}
^{*}University of Toronto, [†]YScope

Abstract

The most widely used programming languages today are managed languages. They are popular because their vast features improve many aspects of code development, including increased productivity and safety. However, as a product or service scales in usage, performance issues become a problem. Developers are then often faced with complex choices as they must decide whether the desired performance can be squeezed from existing code, or whether their language has reached its performance limits, requiring years of code to be ported to a new more-performant language. To make matters worse, runtime performance is shrouded in mystery as it involves complex interactions of different components, such as interpreter, just-in-time (JIT) compiler, thread library, and Garbage Collection (GC) system.

We present an in-depth performance analysis and comparison of Java, Go, JavaScript, and Python, using C++ as a baseline. We carefully instrumented the different language runtimes, so that developers can precisely measure the number of cycles taken to execute any bytecode instruction, or the overhead of dynamic type checking in JavaScript. This allows us to accurately identify sources of overhead. We further created 6 applications from the ground up to establish the *LangBench* benchmark; the applications cover a range of complexity, and they cover a variety of application scenarios differing in compute intensity, memory usage, network and disk I/O intensity, and available concurrency. We comprehensively analyze their completion times, resource usage, and scalability.

Overall, we found that V8/Node.js and CPython exhibit excessive overheads, executing applications 8.01x and 29.50x slower on average than their C++ counterparts, respectively. Making matters worse, applications on these two runtimes scale poorly in that they cannot effectively utilize more than one core. In contrast, OpenJDK and Go applications are performance competitive to C++, running only 1.43x and 1.30x slower, respectively, and they can easily scale to multiple cores. There are applications where OpenJDK and Go outperform their C++ counterparts.

1 Introduction

Programming languages with integrated run-time environments have continuously grown in popularity. The three most popular languages on GitHub since 2015 are JavaScript, Java, and Python [38]. These languages offer the promise of improved developer productivity and thus faster product creation and adaptation because of a variety of features they offer, including easier readability and usability, dynamic type checking, memory management with garbage collection, and dynamic memory safety checks. We use the term “*managed languages*” to refer to these type of programming languages.

Managed languages are increasingly being used to implement *systems software* where performance is critical. Both Hadoop [54] and Spark [76] run on a Java Virtual Machine (JVM) [61] as they are implemented in Java and Scala respectively. Kubernetes [21], etcd (a distributed key-value store [4]), and M3 (a distributed time series database and query engine built by Uber [14]) are all implemented in Go. Recently, even an operating system (OS) kernel, Biscuit [52], was implemented in Go [8]. Openstack [18], Paypal [1], Instagram [22], and Dropbox all heavily utilize Python; Python is Dropbox’s “most widely used language both for backend services and the desktop client app” with almost 4 million lines of Python code in one repository [20]. As a final example, JavaScript is used in the performance critical path for the Bladerunner pub/sub system at Facebook [49].

Several factors come into play when selecting a programming language for a new service, including current developer expertise and experience, constraints imposed by existing ecosystems (e.g., home-grown libraries, development, debugging tools, performance monitoring and logging systems, etc.), and developer productivity. Managed languages are an attractive proposition, precisely because they offer the promise of higher developer productivity, leading to faster project completion times. The performance of the language is rarely a consideration at the outset, in part because of the belief that performance issues can be addressed later, perhaps through horizontal scaling by simply adding hardware. Some go as far as to claim “*Choosing a language for your application*

simply because it's 'fast' is the ultimate form of premature optimization" [47].

However, performance will ultimately become a priority as the usage of the service begins to scale and the service becomes too slow or the cost of hardware becomes too high. Developers then begin a large sequence of performance optimizations that can grow into herculean efforts. For example, Twitch.tv and others use tricks and tweaked parameters to meet desired GC performance in Go [5, 19]; project Tungsten in Spark goes as far as to bypass the JVM, to squeeze out performance [23].

But there can come a point where incremental optimizations (requiring much time and effort) no longer suffice and a more radical solution must be considered, namely switching to a "better performing" language. A few examples from industry: Stream abandoned Python for Go, as Python would spend 10ms creating objects from data that Cassandra took 1ms to fetch, noting that "We've been optimizing Cassandra, PostgreSQL, Redis, etc. for years, but eventually, you reach the limits of the language you're using." Discord switched from Go to Rust claiming that "Rust was able to outperform the hyper hand-tuned Go version." [43]. Performance issues are also cited as the main reason Twitter was forced to switch from Ruby on Rails to Scala and Java [40, 42].

When selecting a new language for performance reasons, the question is: what language? Understanding the performance and scalability implications of a (new) language today is non-trivial, especially for managed languages. This is for several reasons.

First, no empirical studies exist that scientifically compare the different managed languages. The primary source of information available today is the blogosphere containing heated "religious" debates that include tunnel-visioned anecdotes with few rigorous measurements to back up stated claims. For example, while many believe programs written in Java run slower than when written in C/C++ [27], others suggest that Java programs can be faster than C, because the JIT compiler produces faster machine code by leveraging a runtime profile [26]. Similarly, there have been polarized debates with respect to the performance of JavaScript [11, 39], Go [43, 46] and even Python – for example, sources from Paypal claimed that Python offered superior performance over other languages and reported multiple cases where Python outperformed their C++ and Java counterparts while requiring less code [1]. Similarly, developers reported that Python could outperform both C/C++ and Java when using regular expressions or strings [33–35].

Discussions on *scalability* are even muddier. For example, in a popular blog by the official Node.js Medium account, developers conclude that by being event-driven and asynchronous, JavaScript is *ideal* for scaling to millions of concurrent connections, despite its event loop only executing on a single thread [45]. As another example, while it should be well-known that CPython, the de facto runtime for Python today, uses a global interpreter lock (GIL) that will serialize

all concurrent thread executions, Paypal's engineering blog claims that it scales well, and noted that "Dropbox, Disqus, Eventbrite, Reddit, Twilio, Instagram, Yelp, EVE Online, Second Life, and, yes, eBay and PayPal all have Python scaling stories that prove scale is more than just possible: it's a pattern" [1].

Second, no benchmark suite is publicly available today that enables a meaningful comparison between different managed languages (and their implementations). Existing benchmark suites target specific languages or applications. Extending these benchmarks to other languages is often impossible; for example, the DaCapo benchmark for Java contains applications such as Eclipse, a full-featured IDE [50]. As a result, any comparison on language runtime performance often compares apples to oranges.

Third, language runtime systems are extremely complex software systems, providing multiple abstractions that all affect performance. For example, a developer must understand the interpreter, possibly multiple JIT compilers (e.g., the OpenJDK JVM contains 4 levels of JIT compilation), a memory management subsystem that performs garbage collect, the behavior of thread libraries, etc.

Finally, there are no helpful, publicly available profiling tools for understanding the overheads of language runtime systems. The language subsystems themselves expose little profiling information on their internals. For example, while it is widely speculated that dynamic type checking adds significant overhead [44], V8/Node.js does not expose any performance counters to report this overhead.

In this paper, we present an in-depth quantitative performance analysis of four of the popular managed languages with their most widely used runtime systems: CPython, OpenJDK, Node.js with the V8 engine for JavaScript, and the reference Go compiler [15, 24, 36, 38]. We compare their performance characteristics with that of C++ on GCC as the baseline. Our focus is primarily on understanding their differences with respect to speed and scalability.¹ We chose these languages not just because of their popularity, but because they represent different designs along the following three dimensions:

- **Typing.** JavaScript and Python are dynamically typed, meaning the runtime must determine the type of objects at run time, whereas others are statically typed. This allows us to understand the performance impact of dynamic type checking.
- **Execution modes.** Only Go is ahead-of-time compiled. The other runtimes first interpret bytecode, and compile hot functions Just-In-Time (JIT). The exception is CPython that only has an interpreter and no JIT compiler. This enables us to compare three execution modes: native-only (Go and

¹An analysis of resource usage is left to the Appendix, because the findings have largely already been established by prior studies [63], and we did not need to implement any additional profiling mechanisms.

C++), a combination of interpreter and JIT-compiled native (OpenJDK and V8), and interpreter only (CPython).

- **Concurrency models.** V8/Node.js is event driven where event handlers are executed sequentially on a single kernel thread. Similarly, CPython has a global interpreter lock (GIL) so only one thread can execute Python code at a time. Go has its own scheduler and provides *user threads* as “goroutines.” Its scheduler decides how many kernel threads to use for the developer’s goroutines. OpenJDK’s Thread is simply a kernel thread.

Contributions

The contributions of the paper are as follows:

Runtime instrumentations. We are the first to make publicly available (as artifacts) instrumentations for the three runtime systems of popular managed languages that are not statically compiled, namely OpenJDK, V8, and CPython. Implementing such instrumentations is challenging given the complexity of these runtimes and the fact that two of them are implemented in assembly and IR. Our instrumentations enable bytecode-level profiling of (1) the execution overhead of any target *bytecode* in the interpreter and (2) the dynamic type-checking overhead in Node.js/V8. The profiling information generated, in turn, can be used to guide optimization efforts at the application level and can enable effectual optimizations. The instrumentations are described in §2.

Benchmark suite. We are the first to make publicly available (as artifacts) six applications suitable for evaluating managed languages; these applications were used to create twelve benchmarks. The applications, which range from micro-benchmarks to real applications, cover a variety of scenarios, differing in compute intensity, memory usage, I/O intensity, relative startup time, and the degree of available concurrency. In particular, we took care to expose the differences in the three major design dimensions mentioned above. Three of the six applications are parallel, and we parallelize them using both multithreading and multiprocessing where applicable. The benchmark suite is called **LangBench** and is described in §3. The source code of our instrumented runtimes and LangBench can be found at <https://github.com/topics/langbench>.

Comparative analysis. We quantitatively analyse the performance of the benchmarks in our suite and identify how the individual runtimes improve or hinder performance relative to the respective C++ implementations. Our objective was to compare the runtimes of the target managed languages in an objective, scientific way. Many of our results are not particularly surprising (even if they contradict some views held in the blogosphere). For example, Go and OpenJDK perform significantly better than V8/Node.js and CPython, with CPython performing worst by far, even when compared against V8 and OpenJDK’s interpreter-only execution (§6). CPython and

V8/Node.js do not benefit from parallelism; in fact, increasing the number of threads systematically decreases performance (§7). A major source of V8’s relatively poor performance is its dynamic type checking, even when the JS code only uses primitive types that never change (§6.1).

Perhaps more surprising is the fact that in many cases, the abstractions offered by runtimes can actually lead to speedups over GCC (§8). This contradicts the conventional wisdom that abstraction comes at the expense of performance [74]. OpenJDK outperformed GCC in three of the benchmarks, because the moving garbage collector actually improves cache locality. This leads to the unintuitive behavior that the more frequently GC is performed, the *better* the overall performance. Go abstracts away the usage of kernel threads, reducing the number of context switches and kernel threads. Finally, abstracting away low-level I/O operations allows runtimes to use optimal I/O system call configurations, outperforming the idiomatic approach in C++.

Limitations

The main limitation of our work is that it does not, and cannot, comprehensively answer every question one might have related to the performance of a language runtime. We only evaluated the runtimes of four languages, and for each language we only evaluated the implementation that is the most widely used. In addition, we only ran our workloads on a single OS/hardware stack. Our findings pertain to our benchmarks, which model real-life applications, but may not be representative of a vast range of applications. Accordingly, our study is not meant to determine the best or most performant programming language for any particular application. Furthermore, our benchmark and analysis do not focus on some performance aspects. Notably, we do not study the overhead of garbage collection when under memory pressure (there is a gap between the working set size of our benchmarks and the maximum heap size setting). There is a large body of prior work focusing on this aspect already [51, 63, 79]. Similarly, our benchmark is not meant to measure the various JIT compiler’s optimizations, as there are also a large number of existing benchmarks meant to do exactly that [10, 32, 53].

2 Language Runtime Instrumentation

In this section we describe how we instrumented the three runtimes: OpenJDK’s HotSpot JVM, Node.js/V8, and CPython. Our instrumentations measure two types of information: (1) the performance of the execution of any bytecode instruction in the interpreter, and (2) the dynamic type and bounds checking overhead in V8’s JIT compiled code. Users can specify a bytecode instruction to measure its overhead, or any JavaScript (JS) function to measure the type and bounds checking overhead when executing that function.

Why profile interpreter performance? Some have the view that interpreter performance is not important as it mostly affects the startup time, which will be amortized by “warm execution.” We do not share this view. While interpreter performance may have been irrelevant over a decade ago when workloads ran in large, long-running monolithic applications that handle all requests [75], the paradigm shift to the cloud [65, 69, 77] and data analytics [62] expose the runtime’s startup performance as being significant. For example, auto-scaling in the cloud often results in the bringing up of additional instances in the face of a load spike [65, 69]; the problem is also exemplified by short-running instances in Function-as-a-Service platforms [65, 77]. In 2020, the median AWS Lambda invocation ran for only *60 milliseconds* [37], while startup times for the JVM and V8 are on the order of hundreds of milliseconds or even seconds [62, 65, 77, 80]. Similarly, data analytics systems face a fundamental tension between parallelizing long running jobs into shorter tasks and the runtime’s start-up overhead [62].

In practice, instead of ignoring the performance of the interpreter, implementers spend huge efforts in optimizing the interpreter. For example, OpenJDK has two interpreter implementations: one in C++ and the other entirely in hand-crafted x86 assembly; in one benchmark (§6.2), we found that the C++ interpreter to be 1.93x slower than the assembly one, which is perhaps why the C++ interpreter is only used on non-x86 platforms. Similarly, V8’s interpreter is written in hand-crafted IR, and IBM’s OpenJ9 Java runtime has significant optimizations targetting startup time which is featured as a major advantage over OpenJDK in the cloud [55, 69, 75].

Bytecode-level profiling can guide optimization efforts and can enable effectual optimizations. For instance, developers can optimize their programs to avoid the use of bytecode instructions with high overheads. Instagram engineers did just this by instrumenting CPython to identify the bytecode instructions with high overheads, and then optimizing their code to avoid using these expensive instructions [22]. Bytecode-level profiling also allows us to understand the performance difference between different runtimes.

Why profile type and bounds checking? As we will show in §6.1, dynamic type and bounds checking is a major source of V8’s overhead. Similar to bytecode profiling, programmers can optimize their JS programs to avoid such overhead once the source is identified (§6.1). Our instrumentation also enables eliminating type and bounds checking overhead entirely for those functions where developers know that they are safe. For instance, say a JS function accesses `a[i]`, the element at index `i` of array `a`, and their types never change (known as “monotype”). V8 detects that `a` and `i` are monotype, and it speculatively compiles the function: it checks `a` against the array type (instead of other types) and `i` against integer, before accessing `a[i]`.² But to ensure safety, it cannot remove the

checks because their types could dynamically change in the future. In that case, the check will fail, forcing the JIT-compiled function to exit and be destroyed, and V8 will re-execute the function in its interpreter before recompiling it.

By disabling the checking logic in V8’s JIT compiler for any user-specified JS function, we effectively create a significantly more efficient, albeit unsafe, version of the function. In the above example, developers could enable this feature to turn off the checks when they know `a` and `i` are monotype, so the JIT-compiled code will directly access `a[i]` by indexing into `a` without any checks (effectively turning the JS function into a C function). The difference in execution time of applications with and without checked functions can be significant: e.g., in LangBench’s sort benchmark, disabling the checking in V8 results in 8x speedup (§6.1).

Note that we only instrumented V8’s JIT compiler for identifying type and bounds checking overheads, but not its interpreter. This is because unlike the JIT compiler that independently compiles the different functions, the interpreter’s checking logic is applied to all functions equally, leaving us only with the option of either performing checks in all of an application’s functions or none of them. The latter option would likely be too risky to be useful in practice. We further note that the checking overhead in the interpreter also becomes negligible when compared to the other overhead from the interpreter, whereas their proportion become much more significant in JIT-compiled code.

Instrumentation Implementation. Conceptually the instrumentations we use to profile bytecode execution in the interpreters are simple. We locate the code block in each interpreter that processes a bytecode instruction, and inject instrumentation around it to collect metrics from the x86 CPU performance counters. In practice, however, adding instrumentation is challenging. One challenge is the complexity of the runtimes: JVM, V8, and CPython consist of approximately 1.2M, 1.0M, and 0.9M lines of code respectively, with little documentation. Instrumenting JVM and V8 is even more challenging as their interpreters are not programmed in a high-level language (e.g., C++) as the other runtimes are, but are generated dynamically at startup time.

The HotSpot JVM has two interpreters. Its default interpreter for x86 is written in hand-crafted assembly (known as the “assembly interpreter”). It also has a interpreter written in C++. We instrumented both. Instrumenting the assembly interpreter brings three challenges. First, one needs to locate the code blocks that process the different bytecodes by searching the assembly code. Second, one has to carefully ensure that the instrumented code does not clobber any registers that are used by the interpreter’s logic. Finally, HotSpot writes the assembly instructions of the interpreter into memory when it starts up and then jumps to the memory location of the beginning of the interpreter. Hence, we need to use the same mechanism in order to be able to embed our instrumentation logic (written in assembly) into memory.

²It also performs other checks as described in §6.1.

```

1  push rax
2  push rcx
3  push rdx
4  rdtscp      ; saves tsc into EDX and EAX registers
5  shlq rdx,32 ; shift tsc's higher 32 bits up in rdx
6  orq rax,rdx ; or onto rax
7  movq dst,rax ; output to a scratch register dst
8  pop rdx
9  pop rcx
10 pop rax

```

Figure 1: The sequence of assembly instructions inlined into the processing of each bytecode instruction.

Figure 1 shows the instruction sequence we inject as part of our instrumentation to obtain the CPU’s timestamp counter (tsc). Line 1-3 saves the registers values.³ The `rdtscp` instruction saves the higher and lower 32 bits of tsc into EDX and EAX respectively, i.e., the lower 32 bits of RDX and RAX [68]. It also clears the higher 32 bits of RDX and RAX. Line 5 shifts the higher 32 bits of tsc, stored in EDX, to the higher 32 bits of RDX, and line 6 effectively concatenates the higher and lower 32-bits of tsc, and stores it into RAX. We embed this instruction sequence at both the beginning and the end of the processing of the target bytecode instruction, so that we can measure the latency by computing the difference.⁴ Similarly, we use `rddpmc` to read other performance counters, including those for cycle and instruction counts.

Instrumenting V8 is even more challenging. V8’s interpreter is written in hand-crafted intermediate representation (IR). When the runtime starts up, the interpreter’s binary is generated dynamically from this IR by the same JIT compiler used at run time in V8. This required us to instrument both the IR code of the interpreter and the JIT compiler so that native instrumentation code is injected correctly.

Specifically, for each target bytecode, we had to locate its processing logic in the interpreter’s IR and then add a new type of IR node we introduced. We further had to modify the JIT compiler, so that when it encounters this new IR node, it produces the correct assembly instructions that collects the CPU performance counters. This was challenging because there is little documentation describing the internals of V8’s interpreter IR or JIT compiler.

One advantage with JVM and V8 is that developers do not need to recompile the runtime when they wish to profile a different bytecode instruction, but only need to restart the runtime. This is because the interpreters are generated dynamically at startup time. Accordingly, we identify which bytecode instruction is to be instrumented at startup time, generate the appropriate instrumentation code so that it is

³We have to manually save the registers because we directly inject code into the assembly code, in contrast to injecting assembly code into C where the `__asm__` block saves the registers.

⁴Intel allows tsc to be synchronized across multicore [48], and Linux enables this synchronization [13]. This ensures a meaningful counter value even if the interpreter thread is migrated to another core during the processing of a bytecode instruction. In reality, however, migration is rare given the processing of bytecode instruction typically only takes tens of cycles.

embedded in the interpreter when written to memory (as with JVM) or generated by the JIT compiler (as with V8).

Instrumenting CPython is far more straightforward because it is written in C++. However, the CPython runtime will have to be recompiled whenever profiling is to be enabled or the target bytecode instruction that should be instrumented is changed. In theory, one could, before the execution of each bytecode, check whether the bytecode is one of the specified target bytecodes, and conditionally execute the instrumentation, but this would add too much overhead.

Instrumentation Overhead. Although our instrumentation could incur noteworthy overhead when enabled on frequently executed bytecode instructions, we only used them to measure a specific bytecode instruction, instead of end-to-end runtime. We only count the number of instructions inside of the measurement instructions, not including our instrumented instructions. This is possible as we control the exact assembly instructions generated, and we verify said assembly using `objdump`, `gdb`, and outputting the JIT-compiled assembly.⁵

However, our cycle measurements could be skewed by the measuring instructions limiting the processor’s out-of-order execution and pipelining capabilities. This is a limitation, and it is extremely difficult to accurately measure this overhead due to the fact that the very act of measuring the cycle count disrupts pipelining (similar to the observer effect in physics).

3 LangBench

Our goal is to compare realistic applications across different languages. We cannot reuse existing benchmarks as they target specific languages, and extending these benchmarks to other languages is infeasible. For example, porting the DaCapo benchmark requires us to implement Eclipse, a full-featured IDE, in four other languages [50]. Therefore, we chose to build 6 applications from the ground up to cover a variety of workloads. We implemented these applications in each of the 5 languages: C++, Go, Java, JavaScript, and Python. From the six applications, we created twelve benchmarks by varying degrees of concurrency, and exploring alternative implementations of the applications.

We made a best-effort attempt at covering a variety of different types of workloads. Our applications range from micro-benchmarks to real world applications, and they stress three major resource usage categories in different ways, being one or more CPU-intensive, memory bound, and I/O bound. Additionally, we implemented parallel versions of the applications where applicable. They also vary from short running to long running ones. The applications and their categories are shown in Table 1.

It was important to ensure that the applications were implemented in a similar and fair manner in each of the five

⁵There is no overhead for removing the type and bounds checking in V8 as the compiler only removes instructions.

| Application | CPU | Memory | I/O | Parallel |

| File server | | | ✓ | ✓ |

Table 1: The applications and the component(s) they stress.

languages. The design of every implementation of an application is conceptually identical: they use the same algorithms and control flow. Each application is relatively small, so that it could be built in all languages using the same algorithms and data structures. This kept the complexity of the application similar across the languages.

Yet, we fully rewrote the applications in each language, providing our best effort to make the code idiomatic. We referred to official language documentation (e.g. [7]). In certain cases we also implemented different versions of the code. For example, in the JavaScript Sudoku implementation we re-wrote the code multiple times to change the storage of the arrays (see §6.1 for details). For Python and JavaScript we also tried versions that create parallelism (e.g. multiprocessing in Python) and versions that only provide concurrency (e.g. threading in Python). In general, as we analysed each bottleneck, we also tried to find any more performant implementations.

The six applications are:

Sudoku Solver. We implemented an exhaustive search sudoku solver, borrowing from the Spec CPU 2017 benchmark [30]. The algorithm recursively labels all empty cells. At each cell, it verifies the grid state, using the next digit for the cell if verification fails. If all digits are exhausted for a cell, it backtracks to the previous cell.

String Sorting. We implemented the in-place merge sort algorithm described by Katajainen *et al.* [59] and use it to sort strings. First, we permute every possible string of length 6 with 18 possible letters, creating 18^6 strings. These strings are stored in an array, which are then sorted.

Graph Coloring. Graph coloring labels each vertex in a graph, such that no two vertices with an edge between them have the same label. We implemented the algorithm presented by Wigderson [78] which uses a bounded number of colors with run time complexity polynomial in the number of vertices, edges, and the chromatic number. The benchmark colors the YouTube social network and ground-truth communities graph from the Stanford Large Network Dataset Collection [60]. We implemented both a recursive and an iterative version of the algorithm.

Key-Value Store. We implemented an in-memory key-value store based on the general architecture of Redis [28]. We stress the server with Redis’ packaged benchmark by running a SET test followed by a GET test. Each test makes 2 million requests, randomly selecting a key from a space of 500 thousand keys, using a value size of 64 bytes. The Redis benchmark opens

a configured number of client connections to the key-value store. Each connection performs an equal number of requests and is treated as a unit of concurrency (such as a thread). The clients are run on a machine separate from the one running the key-value store.

Log Analysis. We implemented the algorithm of CLP that parses logs by separating highly repetitive static text from variable values, and stores them in two different indexes [73]. Logs are queried, returning the matching log messages by searching the index and raw log. We separate the searching into two separate tests. “Regex” searches the raw logs using regular expressions, whereas “Indexed” searches using indexes. Both tests can be run with parallelism, where the files to be searched are partitioned equally. We process 7000 log files totalling 1.21 GB on disk with an average size of 181 KB. The logs were generated by running various jobs from HiBench [56, 57]. Each test first indexes the logs and then performs 7 queries.

File Server. We implemented an HTTP server that serves static files from a directory. A single C++ client is always used that spawns a configured number of threads; each thread connects to the server and requests an equal partition of 1000 real log files with an average size of 16.8 MB. The server implementations handle these connections concurrently, treating each connection as a unit of concurrency. The client and server run on different machines.

4 Methodology

We ran our experiments on two in-house servers, each having 2 Xeon E5-2630V3, 16 virtual cores, 2.4 GHz CPUs, 256 GB DDR4 RAM and two 7200 RPM hard drives. They are running Linux 4.15.0 and connected by a 10 Gbps interconnect. For C++ programs we used GCC 9.3.0 compiling with `-O3` against the C++17 standard. For OpenJDK 13 [17], CPython 3.8.1 [25], and Go 1.14.1 [6], we used the reference implementations for each respective language. We use Node.js 13.12.0 [16] which uses V8 7.9.317.25 [41].

We ran each benchmark 5 times and report the average. The key-value store, log parser, and file server benchmarks were run with the number of both client and worker threads ranging from 1 to 1024. For OpenJDK and V8 the minimum amount of memory was set by determining the first heap configuration that did not cause a crash; for Go, GOGC was set to 5%. We then continuously increased the heap settings until performance no longer improved. We used the results from the first setting (i.e., the smallest heap size) that resulted in optimal performance. For the log parser and file server benchmarks, the used log files were stored on a distributed file system with a replication factor of 2. We cleared Linux’s page cache before running each benchmark.

Figure 2: Relative completion times for various language implementations normalized to optimized code under GCC. Note the logarithmic scale of the y axis. “LA” refers to the log analysis application. The numbers at the bottom shows the benchmark’s absolute execution time in the C++ implementation. For benchmarks with concurrency, the “Best” bars are annotated with the thread count that results in best completion time. For key-value store and file server it is the number of client threads, not the number of threads used server side. For GCC and OpenJDK, the server creates 1 (kernel) thread to handle each client thread, so the number of server-side threads is the same as the client. For both Node.js and CPython, their best completion time in key-value store is achieved when using a single server-side thread (due to their scalability characteristic described in §7). As for the file server benchmark, both Node.js and CPython’s best performance is achieved when using 64 server-side threads (§7). The number of server-side threads in Go is automatically determined by the runtime as described in §8.2. The number of threads for log analysis is the number of worker threads (as there is no client).

5 Overview of Results

Figure 2 shows the run times for the benchmarks in LangBench. Unsurprisingly, optimized GCC was the *fastest* on average, with Go and OpenJDK close behind, being 1.30x and 1.43x slower than GCC. Impressively, Go and OpenJDK outperform optimized GCC for 3 out of the 12 benchmarks. V8/Node.js and CPython performed the worst with run times 8.01x and 29.50x slower than GCC. At the extreme, CPython was 129.66x slower than GCC (for the sort benchmark). V8/Node.js and CPython were competitive with GCC only when the workload is bottlenecked by disk I/O, i.e., in the file server benchmark.

We also found that V8/Node.js and CPython are limited with respect to achievable parallelism. Their design serializes the threads’ computation, and requires expensive serialization for different threads (V8) or processes (CPython) to communicate. This leads to the unintuitive result that adding additional threads actually slows down parallel applications as more serialization is required. In fact, for both the key-value store and parallel log analysis benchmark, the best performance is achieved using only a single thread. In contrast, both Go and OpenJDK scale to multicores. Go achieves a 1.02x speedup over GCC in the multithreaded key-value store benchmark, despite being slower in the single threaded version.

In the subsequent sections, we use our instrumented runtimes to provide detailed analyses that explain these results. Specifically, for each runtime, we analyze (at minimum) the two worst performing benchmarks, considering both single-threaded (§6) and multi-threaded (§7) variants for those with parallelism. We further analyzed every case where the runtime outperforms GCC (§8).

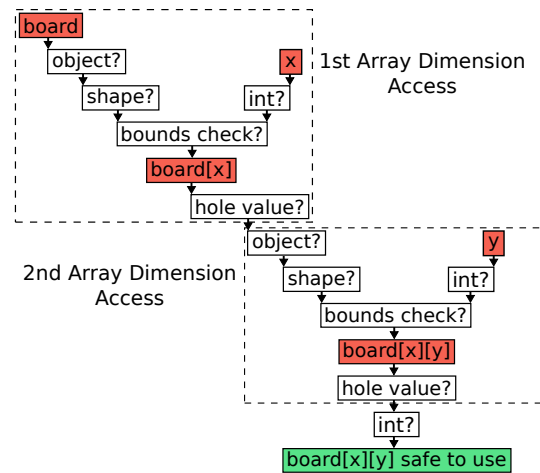

Figure 3: Checks required to access `board[x][y]` in V8/Node.js.

6 Runtime Overhead (Single-thread)

This section investigates the source of runtime overheads on the LangBench single-threaded applications that performed poorly. Specifically, we found (1) type and bounds checking (§6.1) is the bottleneck for V8 in its slowest benchmarks (Sudoku and Sort); (2) interpreter performance (§6.2) is the major cause of CPython’s overhead – despite lacking a JIT compiler, its interpreter performs much worse compared to OpenJDK and V8; (3) GC write barrier (§6.3) is the bottleneck in the Sort benchmark for both OpenJDK and Go, which is their slowest workload, even when heap usage is small.

6.1 Type and Bounds Checking Overhead

We found that type checking and bounds checking made up 41.83% and 87.43% of V8’s execution time in the default su-

| Code Version | Time (s) | Overhead of Checks (%) |
|----------------------------|----------|------------------------|
| Default | 2.369 | – |
| 1-2 Remove Obj./Int Checks | 2.177 | 8.105 |
| 3 Remove Shape Check | 2.219 | 6.332 |
| 4 Remove Bounds Check | 2.154 | 9.076 |
| 5 Remove Hole Check | 2.051 | 13.423 |
| 1-5 Remove All Checks | 1.378 | 41.832 |

Table 2: We modified V8’s JIT compiler and removed each of the checks performed for a 2D array access to `board[x][y]` shown in Figure 3. We measured the resulting execution time, and compare it against the default execution time with all checks. We also show the execution time when all checks are removed.

doku and sort benchmarks, which are the two single-threaded benchmarks where V8 showed the worst performance compared to GCC. Note that V8 has other sources of overhead, such as execution being partially interpreted, when compared with GCC. For the numbers in this sub-section, we compare against the default execution time when the runtime binary is in Linux’s page cache, unlike the results in Figure 2, where we clear the page cache before each test. Next we zoom into the Sudoku benchmark to explain this overhead, and how we can leverage our bytecode profiling information to optimize our JavaScript code.

For V8/Node.js, Sudoku spends 93% of its time primarily comparing 2D array elements of the sudoku board. The majority of this time is spent performing 11 type and bound checks for each 2D array access, as shown in Figure 3. Each dimension requires 5 checks, and the 11th check is used for the final value. Table 2 shows the overhead for these checks.

The first check ensures that `board` is an object pointer, by checking for a tagged bit to distinguish between an object pointer and a primitive integer value. (V8 stores both object pointers and primitive integers in a 8 byte word, so that integers can be stored inline instead of being allocated on the heap.) Second, V8 must similarly check that `x` is an integer, rather than an object. Omitting these checks made it 8.1% faster (shown in Table 2) — removing them is safe, as we know that no incorrect type will be used.

After V8 confirms that `board` is an object, it checks that the internal type of `board`, called a shape, is an array. Fourth, V8 performs a bounds check for the access to `board[x]`. Finally, V8 checks if the value accessed is a “hole”. In JavaScript, arrays may be sparse, meaning not every index has a value. Indexes without values are called holes, which V8 must convert to `undefined` if accessed. The same checks must be repeated to access the second dimension of `board`. To use `board[x][y]`, a last check is necessary to verify it is an integer.

Profiling enabled optimization. Initially, we preallocated the fix-size sudoku board. In V8, preallocated arrays are created sparse as their values are uninitialized, requiring the hole checks. Even though the array was filled with integers before being used, sparse arrays never lose their status.

```
// OpenJDK: bounds check board[x].length > 8
for (int i = 0; i < 9; i++) {
    // Go: bounds check board[x].length > i
    int element = board[x][i];
    ...
}
```

Figure 4: Code showing where Go and OpenJDK perform array bounds checking when accessing `board[x][i]` in a loop.

| | Bytecode | Insn. per BC | Cycles per BC |
|---------|------------------|--------------|---------------|
| OpenJDK | Assembly aaload | 12 | 7.7 |
| | Assembly iaload | 11 | 7.1 |
| | C++ aaload | 33 | 12.5 |
| | C++ iaload | 22 | 11.1 |
| Node.js | LdaKeyedProperty | 90 | 26.3 |
| CPython | BINARY_SUBSCR | 138 | 41.8 |

Table 3: Statistics for array access bytecodes (BC) performed by various interpreters for the sudoku benchmark.

We implemented an optimized version which would create arrays without holes, known as “packed” arrays. This optimized version was 1.48x faster (and is what is shown in Fig. 2). Our optimized sudoku benchmark for V8/Node.js starts with an empty array, then appends 9 `Int8Arrays` to create the 2D sudoku board. This allows V8 to recognize that there are no holes. Using the built in `Int8Array`, preallocation initialized it with the default value of 0, rather than a hole.

Unfortunately, these optimizations cannot be applied universally. First, it presents a trade-off that can only be determined via profiling: while sparse arrays require hole checking, building a large packed array requires many internal resizing operations to grow the array. In addition, typed arrays such as `Int8Array` only exist for certain integral types. For example, it is not possible to preallocate a packed array of strings or any user defined type.

GCC, Go, and OpenJDK. Compared to GCC, Go and OpenJDK must also perform similar bounds checks. However, they avoid the type checking as they are statically typed.

OpenJDK successfully lifts all loop-invariant computations to outside the loop. In the code of Figure 4, OpenJDK determines that the maximum value of `i` used to access `board[x][i]` is 8, and checks if the length of `board[x]` is greater than 8 outside the loop. Go performs the bounds check in each iteration. Further, 2D arrays in OpenJDK contain pointers to 1D arrays, which may be null. However, OpenJDK has an optimization which eliminates null checks, and instead catches them using a signal handler for `SIGSEGV`. On the other hand, Go does not need to perform null checks as its 2D arrays are laid out contiguously in memory like in C.

6.2 Interpreter Overhead

CPython is slower than the other runtimes because it lacks a JIT compiler and so programs are strictly interpreted. There-

fore we further compare the three runtimes by running sudoku on each of them only in interpreter mode. OpenJDK's (assembly) interpreter outperforms both V8 and CPython by 2.59x and 5.34x respectively. This is because static typing allows OpenJDK to avoid the type checks that V8 and CPython must perform. OpenJDK has dedicated bytecodes for accessing different types of arrays (`aaload` for an array of arrays, `iaload` for an integer array). In contrast, V8 and CPython both have a single bytecode (`LdaKeyedProperty` and `BINARY_SUBSCR`, respectively) which must accommodate for any array or dictionary type. Table 3 shows the performance profiling results of different bytecode executions, using our instrumentations.

CPython is still 2.07x slower than V8, even though both of them do dynamic typechecking. As shown in Table 3, CPython uses 138 instructions and 41.8 cycles to execute each byte code instruction (`BINARY_SUBSCR`), whereas Node.js only spends 90 instructions/26.3 cycles to process each byte code instruction (`LdaKeyedProperty`). This is due to the optimizations of V8's interpreter: it is hand-crafted in IR, whereas CPython is implemented in C. Similarly, we found that OpenJDK's assembly interpreter is 1.93x faster than the one implemented in C++.

We found the hand-crafted interpreter implementation made a few notable optimizations. First, it aggressively inlined functions. The CPython bytecode we inspected ended up containing around 5-6 function calls in the common execution path. The equivalent bytecode in Node.js had no call instructions, similar to when all functions are completely inlined. This further enables more aggressive optimization. For example, error handling logic that would be functions in C code can now be grouped together at the end. This leaves the instructions in the non-error paths tightly together and improves cache performance. In addition, developers have a better understanding than the compiler on what the common path is, so that they can manually group the basic blocks that are commonly executed together (and move error handling logic to the end).

Theoretically GCC could also perform the same level of inlining, and developers can manually use `goto` statements to move all error handling logic to after the common-path logic. However, performing aggressive inlining unselectively could hurt performance (increased function size, register pressures, etc.), and excessive use of `goto` could hurt the readability, reliability, and maintainability of the software.

Performance Sensitivity on Interpreters. We observe that an interpreter may amplify the performance overhead caused by small code changes that would only incur negligible overhead in compiled execution. Under CPython, the iterative version of graph coloring ran 1.66x slower than the recursive version, in contrast to the other interpreters. The function performing the iterative algorithm contained 1.54x more bytecodes than the recursive function, resulting in 22% more instructions recorded by `perf`. In contrast, for GCC, switching from recursive to iterative adds only 4% more instructions.

Iterative versions of recursive functions are commonly necessary to avoid stack overflows. Instead of a recursive function call, the iterative function appends the call arguments to an array, and later pops the arguments off the array to perform another iteration of the algorithm. In addition, the iterative algorithm must check if the array is empty at each iteration of the loop. These seemingly simple operations significantly increase the bytecode count and execution time. JIT compilers mitigate these extra operations through optimizations such as reducing the number of redundant checks.

Startup Overhead for OpenJDK and V8. OpenJDK and V8 spend 843ms and 788ms, respectively, in startup in the Sudoku benchmark. Startup is the primary reason for OpenJDK being slower than GCC when running Sudoku, as it is the shortest benchmark. Specifically, 708ms is spent loading the JVM's large binary from disk, while the rest (135ms) is spent in classloading and interpreter execution. In comparison, OpenJDK's warm execution time is only 868ms (when we run the Sudoku benchmark in a JVM that has already been warmed up by running the same benchmark multiple times), whereas GCC's warm execution time is 611ms.

6.3 GC Write Barriers

We were surprised to see that under OpenJDK's default GC setting, it was 10.03x slower than GCC for the Sort benchmark. Sort is also the benchmark where Go performs the worst relative to GCC: 2.14x slower. The source of the slowdown for both OpenJDK and Go is the cost of GC write barriers. This cost occurs despite GC hardly ever running in Sort, as write barriers are necessary to maintain data structures needed to perform GC. Interestingly, for OpenJDK, using the non-default Parallel GC algorithm drops the slowdown to only 2.07x (shown in Figure 2), as it contains fewer instructions. Go's write barrier contains even fewer instructions, and is slightly faster than OpenJDK with Parallel GC.

Write barriers bring a constant cost to pointer writes regardless of how often GC is actually performed. For our in-place merge sort, swapping two elements is the primary source of write barriers. This requires two write barriers, one for each element being written. OpenJDK's default GC algorithm, G1 [12], adds 44 instructions for these write barriers, completely dwarfing the 6 instructions required to swap the elements and 5 for bounds checking. On the other hand, Parallel GC's write barriers only use 5 instructions, 8.8x fewer than G1.

Both Go and G1 require a write barrier to ensure every live object is captured when they perform marking concurrently with application threads. Furthermore, both G1 and Parallel GC in OpenJDK divide the heap into regions and move live objects across regions to compact the heap. For both, write barriers are used to maintain remembered sets, which are used to find and update pointers to moved objects. However,

G1 performs more checks during its write barrier to avoid unnecessary updates to the remembered sets. This avoids work when using the remembered sets to update pointers, and helps minimize pause time.

7 Scalability Limitations

We found that CPython and Node.js limit the degree of parallelism achievable. We first briefly introduce the background of the Node.js and CPython concurrency model and then describe our findings.

Background. Node.js is event driven; by default, it uses a single Node.js thread to drive an event loop and process all incoming events. If the processing of an event blocks (e.g., on I/O), the underlying kernel thread will block, and Node.js's event loop continues with another kernel thread to process the next event. In other words, multiple threads can be blocked at the same time, but CPU execution is serialized. While Node.js supports running multiple Node.js threads (known as worker threads), each runs its own event loop. Hence worker threads *do not* share the heap (to avoid data races); data sharing requires message passing with data being serialized.

In essence, CPython's concurrency model is the same as that of Node.js where multiple kernel threads can block on I/O at the same time, except that it is the programmer's job to create the threads; the threads share the same heap. In CPython's case, CPU computation is serialized by the Global Interpreter Lock (GIL) so that only one thread can use the CPU at a time. CPython also supports `multiprocessing`, forking different processes to avoid the GIL. However, data sharing and communication requires serialization.

Node.js and CPython's scalability on LangBench. We can now explain the scalability patterns of Node.js and CPython. We ran three parallel benchmarks, namely log analysis, key-value store, and file server, under different configurations, including different number of threads, as well as parallelizing them with multiple processes in CPython. In log analysis and key-value store, *the best performance is achieved using a single CPython or Node.js thread*, whereas the other runtimes are able to improve performance by adding more threads.

These two benchmarks, namely log analysis and key-value store, are bottlenecked by CPU or memory accesses, instead of blocking I/O. Therefore, creating multiple threads offers no advantage in Node.js and CPython as their executions are serialized. In the case of Node.js, performance degrades significantly when creating additional worker threads due to the serialization overhead. On indexed search log analysis, Node.js's performance drops 4.7x when we use more than one worker thread. In this benchmark, multiple workers communicate frequently as they share the same dictionaries. Similarly, serialization overhead slows down CPython when we switch to `multiprocess`, resulting in a 4.9x slowdown on the same benchmark. While multiple CPython threads share the heap,

they still introduce thread management overhead compared to using a single thread.

Specifically, in key-value store, CPython can only scale to one client thread (adding additional concurrent client threads will worsen the completion time). In comparison, Node.js/V8 scales up to 96 client threads, even though it only uses 1 Node.js event-loop thread at server side. However, its completion time can not keep improving with more client threads, whereas it still can under GCC, Go, and OpenJDK. Note that the improvement plateaus when the client thread count increases to 160. Even though GCC achieved its best completion time on 512 client threads, the improvement over 160 threads is negligible. This is why in Figure 2, the difference in best completion times is small between GCC, Go, and OpenJDK, even though they are achieved on 512, 256, and 160 client threads, respectively.

In comparison, Node.js and CPython scale well on the file server benchmark. This benchmark is I/O parallel: there is little communication between different threads, and they are bottlenecked by disk I/O. Creating multiple threads (or processes in CPython) thus improves the performance (when there are concurrent client connections).

8 Runtime Advantages

We found that the high-level abstractions provided by the runtimes can, in some cases, result in better performance and scalability. This is counter-intuitive given the conventional wisdom that abstractions generally come at the expense of performance [74]. We discuss three findings: (1) object relocations in OpenJDK's moving GC can result in better cache locality; (2) Go's scheduler automatically maps user threads to kernel threads, and hence abstracts away the direct usage of kernel threads, reducing the number of context switches and the number of kernel threads used; (3) abstracting away the low-level I/O operations allows runtimes to use the optimal I/O system call configurations.⁶

8.1 GC Improved Cache Locality

OpenJDK's moving garbage collector can significantly improve cache locality, resulting in speedups in three benchmarks: single threaded key-value store and both iterative and recursive implementations graph coloring. In particular, OpenJDK was much faster than GCC at the single threaded key-value store, with 1.46x speedup. This is the largest speedup any runtime had over GCC.

Key-value store. We found that the source of cache locality was from iterating over linked lists. Our key-value store implements a hashtable with separate chaining, meaning hash

⁶There are a few more cases where runtimes demonstrated better performance than GCC; they are related to the implementation of libraries. We discuss them in detail in the Appendix.

Figure 5: The key-value store before and after a GC pause. White boxes logically represent Java objects, and the shaded boxes represent the objects’ location in the JVM heap. A ‘B’ denotes a bucket mapped to by the hash function, and an ‘N’ denotes a node in the bucket’s linked list. The number of the node represents the order they are inserted into the hashtable. The memory for the nodes of the bucket begins scattered, but after GC relocation is ordered by the traversal of the bucket’s linked lists.

Figure 6: The OpenJDK single threaded key-value store benchmark run with increasing heap sizes, corresponding to fewer GC cycles.

collisions are added to a bucket by appending the key-value (KV) pair to a list. This is shown as the white boxes in Figure 5. For example, N2, N3, and N6 are different KV pairs hashed to the same bucket B1.

OpenJDK uses bump pointer allocation. Therefore, nodes in the hashtable are laid out sequentially in memory based on their insertion order. Figure 5 (a) shows how the nodes of a bucket would be initially laid out in memory. There is little locality, as adjacent nodes of the same linked list are scattered. Therefore, whenever there is a lookup, insertion, or a deletion of a key in the linked list, the traversal of the linked list is expensive due to poor locality.

However, OpenJDK’s moving GC reorders the objects in memory. It scans for all live objects that are reachable from the GC roots (e.g., objects on the stack) by following the pointers, copying them to a different memory region, before freeing the old region. For the linked list, this means that the objects will be allocated adjacently, in the same order as in the linked list, as shown in Figure 5 (b).

In comparison, GCC uses a size segregated allocator (`malloc`). Since nodes have the same size, they will be placed in the same region, resulting in a similar pattern as with bump pointer allocation, with nodes laid out in insertion order. When profiling the iteration, we found that GCC actually executed fewer instructions than OpenJDK, but was still slower. In the tight loop iteration, the bucket GCC took only 5 assembly instructions compared to OpenJDK’s 11.

This behavior presents the unintuitive case where the more

frequently GC is performed, the better the performance. Figure 6 shows that with more frequent GC cycles, objects are re-ordered in memory more often, leading to improved performance. We control the frequency of GC by using different heap sizes. The larger the heap, the fewer GC cycles. When it is 128 GB, performance is the *worst* because GC is never triggered; objects are never moved, so there is no locality.

To verify that cache locality was the source of the performance gap, we modified OpenJDK to expose a method to print the virtual address a reference points to. We do this as GC obfuscates `perf` cache hit rates, making them impractical to compare. In one run where no GC was performed, over 99% of the distances between nodes of the linked lists were different, with a median distance of 724 KB. A run with GC was 1.86x faster; 57% of nodes were 88 bytes apart, and 41% were 192 bytes apart. Although the size of a cache line on our processors is 64 bytes, so two nodes would not be in the same cache line, it is likely that they are in adjacent cache lines, opening the opportunity for prefetching.

Graph coloring. We found OpenJDK outperformed GCC (by 1.37x) on graph coloring, when the C++ program uses the standard library. Our investigation showed that GC had a similar effect as for the key-value benchmark given that graph coloring also uses a hash table. Both hash table implementations on OpenJDK (`HashMap` and `HashSet`) and C++’s standard libraries (`std::unordered_set` and `std::unordered_map`) use an open hashing design; i.e., it uses separate chaining to connect the elements in a linked list upon collision. As a result, both GCC and OpenJDK suffer from poor locality initially. However, OpenJDK quickly gains locality through GC, as with the key-value store benchmark.⁷

8.2 Scalability in Go

In the multithreaded key-value store implementation, Go has a 1.02x speedup compared to GCC, despite being 1.16x slower than GCC in the single threaded version. Go outperforms GCC by avoiding 2.2 million context switches through the use of asynchronous networking I/O and significantly fewer kernel threads. With GCC, network I/O is performed using synchronous system calls, blocking the kernel thread, resulting in a context switch. When goroutines perform I/O, the work is offloaded to an internal goroutine which uses asynchronous system calls. A goroutine performing I/O is blocked by Go’s scheduler, but the underlying kernel thread is not blocked; instead, Go schedules another goroutine on the same kernel thread. As a result, Go only uses at most 42 kernel threads, regardless of the number of concurrent client threads. (The number of kernel threads is automatically chosen by the Go runtime depending on the workload’s characteristic.)

⁷We optimized our C++ benchmark by switching to hashtable implementations from Google’s `Abseil` library [2], which uses a closed hashing implementation that achieves better locality.

We verified that context switching causes the majority of the 600 ms gap between the fastest multithreaded Go and GCC execution times. Using LEBench [72], we measured the average cost of a context switch on our machine to be 5.84 μ s. With 32 cores, `perf` reports approximately 70K context switches per core, which adds up to 409ms of overhead, making up the majority of the 600ms performance gap.

8.3 I/O System Calls in the File Server

To read a file in the file server benchmark in C++, we initially used the more general, idiomatic approach which uses iterators. This results in repeated fixed size `read` system calls. Unlike C++, all the managed runtimes abstract away the low-level system call interfaces when performing I/O, so that they can transparently issue system calls in an optimal way, by first calling `fstat` to get the file size, followed by a *single read* for its entire contents. All runtimes use this approach when reading a file. So any developer using the runtimes will benefit from the optimizations without any burden of knowledge. In comparison, we have to manually optimize our C++ implementation to switch to `fstat` and `read`, leading to a 2x speedup.

9 Related Work

Ours is the first performance study to analyze and compare the implementations of multiple widely used runtimes, and provide the necessary instrumentations to do so. There are existing benchmarks to evaluate software performance, but they focus on novel benchmark methodologies. Marr *et al.* designed a benchmark suite with the goal of having a methodology for evenly comparing a common subset of language abstractions [64]. They limit their applications to a minimal set of primitive operations and exclude built-in data structures such as hashables to ensure that no language has an advantage. Rather than strictly stressing the compiler on specific primitive operations, we evaluated all aspects of a runtime on how they affect performance under different scenarios using idiomatic code. Both DaCapo [50] and Renaissance [70] created benchmark suites consisting only of Java applications for various workloads. TailBench created a statistically sound methodology for measuring latency-critical applications in C++ and Java [58]. SPEC [31] and the Computer Language Benchmarks Game [3] provide a variety of benchmarks, covering many languages, but present no analysis. In contrast, our work focuses on understanding and providing an explanation for the technical details of language implementations that cause performance differences.

Other studies of languages have had different scopes, focusing tightly on a specific language or aspect. By utilizing the Rosetta Code [29] repository, Nanz *et al.* present statistical findings, such as the fact that scripting languages are more concise than procedural languages [67]. Nanz *et al.* further

studied the usability and performance of Chapel, Cilk, and Go in multicore workloads [66]. Prokopski *et al.* study interpreter code-copying optimizations in the SableVM, OCaml, and Yarr interpreters [71]. Wade *et al.* quantify the impact of profile data on JIT compiled code quality in the HotSpot VM.

Lion *et al.* instrumented the JVM to measure startup times (i.e., the total time spent in class loading and interpreter) [62]. However, they did not provide fine-grained instrumentation to profile the execution of each bytecode instruction.

10 Concluding Remarks

We presented an in-depth performance analysis of runtimes under a variety of scenarios. We implemented LangBench, a benchmark suite that enables an objective comparison of language implementation performance. Our runtime instrumentations facilitate understanding *why* a runtime performs well or poorly. We demonstrated that our instrumentations provide valuable profiling information that enables optimizations. We have open-sourced our instrumentations and LangBench so that practitioners can use and enhance them to analyze and optimize their applications.

Appendix

We discuss two additional results in the Appendix: (1) memory usage analysis of different runtimes on LangBench, and (2) other speedups from the runtimes over GCC.

Resource Usage: Memory

Figure 7 shows the peak memory usage of the different runtimes. Compared to Figure 2, it also shows the completion time under the minimum memory usage configuration (e.g., the heap size setting in OpenJDK) of each benchmark. Recall that, for OpenJDK and V8, the minimum amount of memory was set by determining the first heap configuration that did not cause a crash; for Go, GOGC was set to 5%. We then

Figure 7: Relative completion time and peak memory usage for various language implementations as a multiplicative factor compared to optimized code under GCC. Each benchmark uses the most optimized version for that language implementation.

continuously increased the heap settings until performance no longer improved. Peak memory was measured using the reported maximum RSS from `getrusage`.

The figure shows that all language implementations use at least 2x more memory than GCC. The more complex runtimes are the worst offenders with V8/Node.js and OpenJDK using 3.70x and 3.38x more memory than GCC on average. Go and CPython use less memory, but still use 2.12x and 2.08x more memory than GCC on average. (As an exception, Go surprisingly manages to use 0.59x less memory than our idiomatic C++ version of the sudoku benchmark.) It is crucial for these runtimes to trade off increased memory usage and performance. Optimal performance can require increased memory usage, which prevents jobs from being scheduled when datacenters allocate resources to fit peak usage. This additional memory is also rarely returned to the OS causing reduced memory utilization.

For both OpenJDK and V8/Node.js, the two runtimes that require the most memory to achieve optimal performance, their worst case was the sudoku benchmark with OpenJDK using 10.94x more memory than GCC. The sort benchmark has the lowest memory usage with GCC only requiring 3.42MB. However, OpenJDK and V8/Node.js also had benchmarks that did not have any memory overhead when compared to GCC. Both runtimes used the same amount of memory as GCC for the key-value store benchmark, despite it being the next smallest benchmark with GCC requiring only 33.43MB.

CPython’s peak memory usage was the closest to that of GCC, but requiring 2.12x more memory on average. It also had the lowest worst case, requiring 4.06x more than GCC for the sort benchmark. Despite being more memory efficient than the other runtimes in most of the benchmarks, CPython still used more memory than any other runtimes in the sort benchmark. Go was also able to use less memory than CPython for the sudoku and graph colouring benchmarks.

In fact, Go was the only language implementation able to use noticeably less memory than GCC, using 0.59x less in the sudoku benchmark. Upon inspection this stemmed from our version of the benchmark using the C++ standard library. The complete C++ version peaks at 3.46MB of RSS, but almost all of this memory is allocated immediately upon running the program. We found that using a C++ implementation that did not use `iostreams` but instead used `open` and `read` reduced the memory usage to 2.72MB. However, the largest improvement was from not linking the C++ standard library by removing the `-lstdc++` flag when compiling. This dropped the usage to 1.33MB and well under Go’s 2.05MB.

Runtime Speedup from Library Implementations

In addition to the cases discussed in §8, there are other cases where managed runtimes performed better than GCC. Go performed better than GCC on the indexed search log analysis

benchmarks, taking 0.90x and 0.93x less time for the single and multithreaded versions, respectively. Further, V8 has the same performance as GCC on the single-threaded regular expression based log analysis. In both cases, the good performance comes from the library implementation of pointer copying (in the case of Go on indexed log analysis) and the regular expression engine (in the case of V8 on regular expression based log search).

Surprisingly, whereas Go spends a total of 0.04 seconds in a critical section in indexed log search, GCC takes 2.49 seconds. In the log analysis benchmarks, each worker thread returns a list of matched log messages to the main thread by appending a thread local list of results to the main thread's global list, while holding a lock. Inside this critical section, for the append operation, Go copies more pointers per loop iteration than GCC.

In Go, appending to a list (referred to as a slice) is done efficiently because slices are an intrinsic type and appending is performed by a builtin function, which uses hand written assembly. Both GCC and Go use 128-bit wide XMM registers [9] to move two 64-bit pointers at a time with a single `mov` instruction. The assembly in Go unrolls the loop as much as possible, using all 16 XMM registers to move 32 64-bit pointers per iteration. Furthermore, rather than checking if a write barrier is required for each pointer, Go checks once if write barriers are required for all pointers, as they do not need to be performed when concurrent marking is not active⁸.

For the same operation in C++ with `std::vector`, GCC only moves 2 64-bit pointers in a single XMM register per iteration. Therefore, for every 2 pointers (or single XMM register move) GCC must also execute a compare and jump instruction to iterate the loop. On the other hand, Go will only execute these two loop iteration instructions every 32 pointers (16 XMM register moves). Furthermore, because we use `std::unique_ptr`, GCC must set the pointers in the thread local vector to `NULL`, as ownership has been transferred to the global vector. GCC stores `NULL` to 2 pointers each iteration of the loop using another XMM register.

⁸Write barriers are explained in more detail in Section 6.3.

Automatic Recovery of Fine-grained Compiler Artifacts at the Binary Level

²Zerpoint Dynamics

Abstract

Identifying a binary's compiler configuration enables developers and analysts to locate potential security issues caused by optimization side-effects, identify binary clones, and build compatible binary patches. Existing work focuses on identifying compiler family, version and optimization level of a binary using semantic features and deep learning techniques. Unfortunately, in practice, binaries are an amalgamation of objects and functions that can be compiled at different optimization levels with a variety of individual, fine-grained, optimizations that may be applied depending on the structure of the code. Hence, rather than recovering high-level artifacts, i.e., compiler family, version, and optimization level, we explore the recovery of individual, fine-grained, optimization passes for each function in a binary. To do so, we develop an approach using specially crafted features alongside intuitive and understandable machine learning models. Our evaluation on 15 popular open-source repositories shows that our approach compares favorably with the state-of-the-art deep learning approach in compiler family, compiler version and optimization level identification. For fine-grained optimization passes, our evaluation on 149,814 functions from 552 binaries in four popular open-source repositories shows that our approach achieves an average F-1 score of 92.1% for all optimization passes and an average F-1 score of 89.8% for optimization passes that could have negative impacts on security. Moreover, our approach includes experimental support for dynamic feature extraction via binary emulation, and our results show that such features offer promising potential in improving the accuracy of optimization pass identification.

1 Introduction

Modern compilers serve much more than simple translators that convert human-readable program code to machine instructions. They are also fully automated optimizers that improve the performance of code via numer-

ous translations, including the removal of unused code, re-ordering of instructions, replacing expensive computations with more efficient ones, and merging functions. Ideally, these optimizations do not change the behavior of the program in any way, other than making the resulting code faster and smaller.

However, while compiler optimizations are performed in ways that should not interfere with the normal execution of a program, some optimizations could have a negative impact on security. In fact, recent studies [3, 19, 21, 22, 24] have shown that certain optimizations could nullify protections and verification of secure functions as well as introduce timing side channels. For example, the dead code elimination optimization could remove instructions that erase sensitive data after using it, causing the sensitive data to be vulnerable to leakage if there is a memory error later on in the program. Similarly, the strength reduction optimization that replaces expensive operations with more efficient ones could open side channels. Developers are usually unaware of these optimizations because the compiler automatically chooses the set of optimizations to apply based on the optimization level, code structure, target architecture, and target processor family. Moreover, even subtle changes can create additional code reuse gadgets, causing the compiled program to be more vulnerable to attacks [1].

One way to avoid these pitfalls is by having developers manually tweak their compilation scripts to avoid applying potentially risky optimizations to secure functions that handle sensitive data. However, for large projects, this would be a daunting and tedious task. In order to maximize performance while avoiding risky optimizations, developers need to manually tweak optimization flags in addition to the optimization level. With hundreds of both architecture-independent and architecture-dependent flags, manually tweaking optimization flags is challenging and time-consuming [5]. Moreover, some compilers also include hidden optimizations that cannot be manually controlled, and the code base for mod-

ern compilers is too large for users to review and study for the logic behind optimizations [7]. In practice, developers for security-critical projects, such as OpenSSL and mbed TLS, take another approach by implementing workarounds in the source code of secure functions to “confuse” the compiler such that it does not apply optimizations to the secure code [19, 21, 24].

These workarounds, however, are not always stable. As compilers introduce more optimizations in each release, a workaround that successfully tricks one version may not be effective for a future version, and developers then need to implement a more complex workaround [19]. Therefore, a solution that helps identify optimizations applied to a binary at the function level could offer significant practical value: developers could use such an approach to, for example, verify that the program is compiled using optimizations that do not negatively impact security before releasing the binary.

In addition to safety verification, compiler optimization classification could be beneficial to binary code clone detection and binary patching. Compiler configurations can cause significant degradation in the performance of clone detection techniques [6, 8, 10, 12]. Similarly, in binary patching [4], locating the vulnerable function to be patched becomes more difficult in the presence of certain compiler optimizations.

Facing some of these challenges ourselves when trying to safely perform binary patching at a function level, we revisited the state of the art in compiler artifact recovery. We found that the most comprehensive of these techniques [2, 16, 17, 20] focus on identifying the compiler family, the major compiler version, and the optimization level for a binary, either for individual functions or for the entire binary — but, we need more detailed information (i.e., the passes that may have been applied). Unfortunately, this level of recovery has not been well explored, and even when it has been mentioned, the authors conclude that “[f]urthermore, some flags would be challenging, if not impossible to detect, the dead code elimination flag being one example” [15].

Additionally, we found that contemporary approaches rely on either semantic features (e.g., the control flow graph) or employ deep learning. As the interpretability of the outputs was a key motivating factor for us, we instead opted for the use of shallow learning with specially crafted features. To our surprise, our approach performed on par with or better than the state of the art [20] that uses highly-tuned neural networks for optimization level identification (e.g., `-O1` versus `-O3`). More importantly, we take a step further and show that contrary to recent statements by Pizzolotto and Inoue [15], one can detect the application of certain optimization passes with good accuracy. Our approach, coined *PassTell*, helps identify optimization passes that affect security for individual

functions, such as different forms of dead code elimination, code motion, and strength reduction passes.

Our specific contributions include:

1. We designed PassTell, a new approach in compiler configuration identification that recovers the optimization passes applied at the function level.
2. We explored the effects of using dynamic features extracted by force-executing each function. We show that the use of such features offers potential in improving accuracy, albeit in certain cases.
3. We evaluated our machine learning approach and compared the results with the state-of-the-art. We find that our approach performs on par with the state-of-the-art in identifying compiler family, compiler version, and coarse-grained optimization level.
4. We evaluated our approach using four variants of 138 programs from four open source repositories built with the latest development version of the Clang 14 compiler. Our approach is capable of identifying most optimization passes with high accuracy.

2 Background

2.1 Compiler Optimization

Modern compilers (e.g., GCC, LLVM, and ICC) offer complex optimizations that improve the performance and reduce the code size of the compiled program. In theory, these compilers provide different levels of optimizations, and programmers only need to specify an optimization level for the compiler to automatically apply the corresponding set of optimizations.

In practice, however, optimization is more complicated than simply applying a fixed set of optimizations passes for each optimization level. The LLVM compiler [11], for example, uses pass managers to control the passes to apply as well as the order of running the passes. The pass manager considers multiple factors when deciding the passes to run in addition to the optimization level specified by the user, including the target architecture, the target processor generation, and the source code structure. For example, for programs targeting outdated x86 processors, the compiler would avoid applying optimizations that use the AVX instructions that were recently introduced, and for functions without loops, the pass manager would avoid running optimizations that improve loop performance. Therefore, knowing the optimization level of a binary is *not* enough to determine the exact set of optimizations applied to the binary.

2.2 Security Implications

While compilers can take care to ensure that their optimizations do not change the behavior of normal program execution, fully automated reasoning about the purpose of deliberately ineffective or seemingly useless operations added by the developers is not (yet) possible. Hence, such instructions are targets for optimization, potentially undermining security assumptions. D’Silva et al. [3] called this problem the “correctness-security gap” and defined three types of security violations caused by compiler optimization: persistent state, side channel attacks, and undefined behavior.

A persistent state violation is when data persists outside of the scope it is designed to be available. D’Silva et al. [3] listed three optimizations that could cause this violation: dead code elimination, function inlining, and code motion. For example, in a password verification function where the password is temporarily stored in the memory during verification, the compiler may consider the operations that erase the local memory to be dead code and remove them, causing the password to exist in the memory after it is used, until it is eventually overwritten by a later function. Similarly, if a trusted security-sensitive function is inlined in an untrusted function, then the lifetime of the local variables of the trusted function would be extended to when the untrusted function returns. Finally, code motion may switch the order of instructions to avoid unnecessary computation or to improve locality. This optimization may cause the program to write sensitive values to memory before verifying that the operation is needed. Beside these three optimizations, Simon et al. [19] added that in situations where the entire stack frame needs to be erased, any optimization that changes the size or the layout of the stack frame such as tail-call optimizations may cause the erasure to be incomplete.

Compiler optimizations could also introduce side-channels that leak information about the program’s execution based on its timing or memory usage. To avoid side-channels, the developer may add unnecessary or inefficient operations to functions, but the optimizations may simplify or remove these operations, thereby reintroducing the side-channel. D’Silva et al. [3] listed three optimizations that could introduce side-channels: common subexpression elimination, which merges multiple instructions into one instruction to avoid duplicate computation; strength reduction, which replaces expensive instructions with more efficient ones, and peephole optimization, which inspects surrounding instructions to find opportunities to reorder or replace instructions for simpler computation or better locality.

Our work focuses on identifying optimizations that could cause persistent state violations or side-channels. Identifying undefined behavior (i.e., violations caused by

undefined behavior when developers use semantics that are undefined by the specification) is out of scope.

3 Related Work

Rosenblum et al. [18] presented seminal work in the area of compiler identification from binary files. Their approach focuses on identifying only the compiler family for code snippets in the IA-32 architecture using a probabilistic graphical model. Later on, Rosenblum et al. [17] extended that work and presented Origin, a tool that identifies compiler family, compiler version, and optimization level for each function in a binary. Origin uses a linear support vector machine model with features including idioms of instructions, sub-graphs of the control-flow graph, and high-level layout of functions such as the starting address. However, for optimization level, Origin could only perform coarse-grained identification with two options: “low” for `-O0`, `-O1`, and “high” for `-O2`, `-O3`.

A few years later, Rahimian et al. [16] presented a different approach (called BinComp) for compiler provenance identification. BinComp focuses on identifying the compiler family, compiler version, and optimization level for the entire binary. Different from Origin, BinComp heavily utilizes features extracted from utility functions added by the compiler to identify the compiler version and optimization level. These utility functions include program initialization, the startup code, and the termination code. While these functions could be highly indicative of an optimization level, it is impossible to perform identification for each function in a binary. Therefore, BinComp could only identify the compiler configuration used to compile the main routine of a program.

More recent work [2, 15, 20, 23] in compiler provenance identification started using neural networks for classification. Chen et al. [2] presented HIMALIA, a classifier using recurrent neural network to identify the optimization level for each function of a binary. HIMALIA uses vectors of disassembled instructions as features and uses two recurrent neural networks for classification. One network classifies the function into one of the four classes: `-O0`, `-O1`, `-O2/O3`, and `-Os`; the other network then differentiates `-O2` and `-O3`. While the evaluation of HIMALIA includes binaries compiled with different versions of the LLVM Clang compiler, it only focuses on identifying the optimization level of each function, making no distinction of optimizations applied in different compiler versions. Yang et al. [23] presented BinEye, a classifier using convolutional neural network to identify optimization levels for each object in ARM binaries. Since each instruction in the ARM architecture is four bytes, BinEye uses the first 1024 instructions of each object as raw features and extracts word and position embeddings from them. Tian et al. [20] presented NeuralCI,

a classifier with either convolutional neural network or recurrent neural network to identify the compiler family, compiler version, and optimization level for each function in a binary. NeuralCI uses Word2Vec [14] embedding to allow instructions with variable size. Similar to BinEye, the evaluation of NeuralCI combined `-O2` and `-O3` into one coarse-grained optimization level of `OH`.

Most recently, Pizzolotto and Inoue [15] presented an approach that uses either a convolutional neural network or a long-short term memory network to identify the compiler family and optimization level for code snippets of 2KB in seven different architectures. This approach includes either the raw bytes or the opcodes as features but concluded that raw bytes lead to better results when large amounts of training data are available. Similar to HIMALIA, the evaluation of this approach includes five different optimization levels: `-O0`, `-O1`, `-O2`, `-O3`, and `-Os`. As NeuralCI performed the most in-depth and realistic evaluation, and it was shown to outperform the other approaches that classify at the function level, we select it for comparison later on in this paper.

4 Approach

We now present PassTell, an approach for identifying the set of optimization passes likely applied to each function in a binary file. Figure 1 shows the overall workflow.

4.1 Dataset Generation

Our dataset used to train the classifier includes functions compiled with different optimizations. Each function includes a set of optimization passes that were applied during compilation and the instructions in the function. The overall workflow of dataset generation is as follows: first, we compile programs with different optimization levels and record the list of optimizations applied to each function; then, we disassemble the binary to retrieve the instructions of each function; finally, we sanitize the instructions by removing detailed memory addresses, call targets, and immediate values.

To train and evaluate our classifier, we first need to gather the optimization passes that modify a function during compilation. While the Clang frontend of the LLVM compiler [11] has an option to list the optimizations applied to each function during compilation, this option outputs all passes that run, even the ones that make no modification. Therefore, we made modifications to extract the optimization passes that modify a function during compilation. Section 5 discusses the modifications we made to the LLVM compiler.

After disassembling the binary file, we sanitize the instructions before feature extraction. Specifically, we replace all memory addresses with the `#MEM#` label, all

call targets with `#TARGET#`, and all immediate values with `#IMM#`. We make this adjustment because the detailed memory addresses, immediate values, and call targets are highly variable across different programs and are not useful in optimization classification. Tian et al. [20] applied similar rules to the instructions.

4.2 Dynamic Feature Generation

As an extension, we also present a method to extract changes of register values (recovered via emulation) and use these dynamic features in our classifier. At present, the dynamic features only include register deltas. We use a binary emulation library to attempt to force-execute each function in the dataset. After the execution of each instruction, we record the address of the instruction, the registers changed, and the deltas of their values. Within these three types of data, the instruction address is only used to compute the coverage of the force-execution and to avoid endless loops.

While it may seem unnecessary to include dynamic features as the dataset already includes the entire disassembly of the function, we posit that dynamic features could still contribute to the classification because some changes in the registers are implicit and not shown in the disassembly. For example, the `FPSW` register includes flags, the stack address, and the current code for floating point operations. Additionally, floating point operations may cause this register to change implicitly. Our main goal of including dynamic features is to explore their potential to improve classification accuracy. We expect progress can still be made in future work.

4.3 Feature Extraction

| Category | Feature Type | Example |
|----------|------------------------|----------------------------|
| Static | Opcode | <code>call</code> |
| | Instruction | <code>mov esi ecx</code> |
| | Register | <code>rsi</code> |
| | 2-gram of opcodes | <code>pop ret</code> |
| | 2-gram of instructions | <code>pop rbp ret</code> |
| | First instruction | <code>push r15</code> |
| Dynamic | Last instruction | <code>xchg ax ax</code> |
| | Register value delta | <code>rbp=-248</code> |

Table 1: Feature types and examples for each type of feature used in our approach

By default, we use seven types of static features: opcode, instruction, register, two-gram of opcodes, two-gram of instructions, and the first and last instruction of a function. The register value delta is an optional feature. Table 1 lists an example of each feature type.

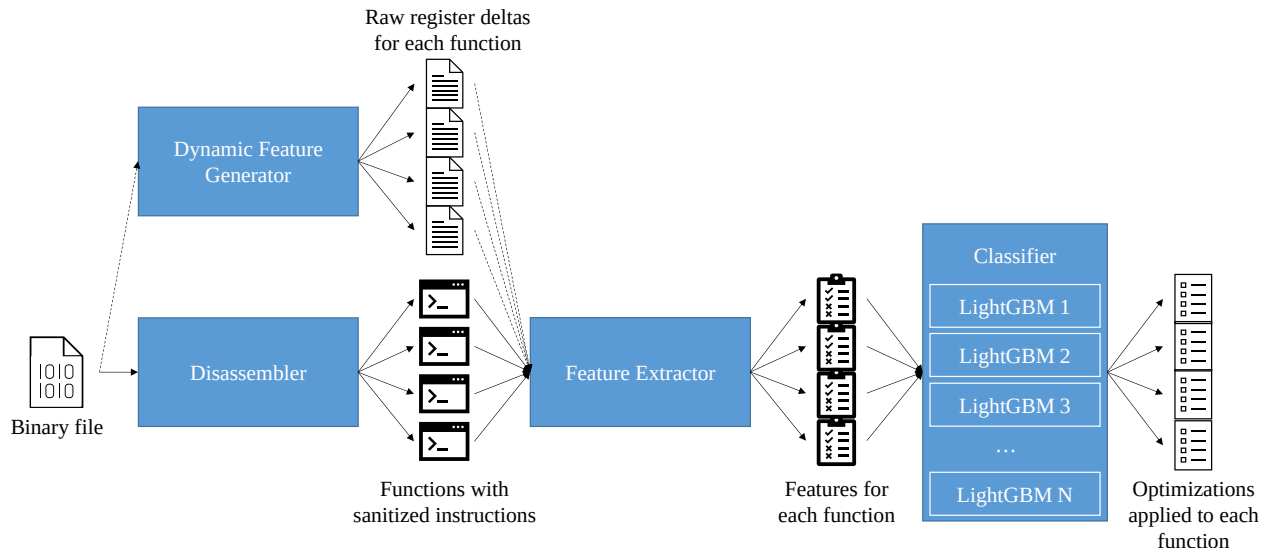

Figure 1: Workflow of PassTell for optimization pass classification

We apply feature selection before extracting features. There are overwhelming amount of different instructions, two-grams of opcodes, two-grams of instructions, and changes of register values, so we select 1,000 features from each of these four feature types, for each optimization pass. This means that we use different features for the classification of each optimization pass. Our feature selection strategy for each optimization pass is as follows: first, we filter the dataset such that it is balanced for the optimization pass (i.e., the number of functions with the optimization and the number of functions without the optimization are the same); second, we sort the features by the number of functions in the balanced dataset that have at least one occurrence of the feature; finally, we select the 1,000 most frequent features of each type. Table 2 shows an example of the selected features for the `Early CSE` pass. For the other feature types, including opcode, register, the first instruction, and the last instruction, we use all features in these types without applying feature selection because there are less features in these types.

All features hold binary values. That is, we check whether the function has this feature or not. For example, a leaf function (i.e., a function that does not call any other functions) that performs arithmetic operations in a loop should have value 0 for the opcode feature `call` because it does not include any call, and it may have value 1 for the opcode feature `test` because it may use the `test` instruction to determine the end condition of the loop.

We decide to use this simple set of binary features as a result of interpretable feature engineering. Our approach with interpretable feature importance allows us to compare and select the most efficient and effective feature types. We also tested using frequencies as features instead of binaries but found minimal improvements.

4.4 Classification

After generating the feature set, we then train our classifier for optimization classification. For each optimization, we train a binary LightGBM classifier [9] that decides if a function is modified by this single optimization.

LightGBM is an implementation of gradient boosting decision tree. We select this classifier instead of deep learning techniques for two reasons. First, modern compilers include a large amount of passes. In our dataset, for example, we observed a total of 83 unique compiler passes applied to functions or components inside a function (e.g., a loop). Each pass requires a separate binary classifier. Therefore, in order to train the dataset with a reasonably large dataset, our choice of classifier should scale well in both training time and memory consumption. Second, classifiers such as support vector machines and neural networks cannot easily demonstrate the reasoning or the importance of features. Decision tree-based classifiers, on the other hand, can more readily show the reasoning and the importance of features.

In the training phase, a list of all optimization passes is generated and a model for each is created. That is, for each function, we create a list of binary labels for each pass to indicate if the function was modified by each of these corresponding passes, then a LightBGM-based classifier is trained for each of those binary labels (i.e., 83 classifiers in total) using the extracted features. For classification, the feature extractor sends each function's features to each of the 83 trained models. The trained model for each optimization pass then decides if that optimization was applied to (and modified) each function, and finally the list of all applied optimization passes is returned for each individual function in the binary.

| Static | | | | Dynamic | | | |
|--------------------------|-------|------------------------|-------|---------------------------------------|-------|----------------------|-------|
| Instruction | | 2-gram of Opcodes | | 2-gram of Instructions | | Register Value Delta | |
| Feature | Count | Feature | Count | Feature | Count | Feature | Count |
| <code>ret</code> | 2,626 | <code>mov; mov</code> | 2,577 | <code>pop rbp; ret</code> | 1,517 | <code>ip=3</code> | 2,710 |
| <code>call #T#</code> | 2,300 | <code>pop; ret</code> | 2,413 | <code>push rbp; mov rsp rbp</code> | 1,059 | <code>rip=3</code> | 2,710 |
| <code>add #I# rsp</code> | 1,688 | <code>push; mov</code> | 2,069 | <code>add #I# rsp; pop rbx</code> | 841 | <code>eip=3</code> | 2,710 |
| <code>push rbp</code> | 1,572 | <code>mov; call</code> | 2,059 | <code>mov rsp rbp; sub #I# rsp</code> | 814 | <code>rsp=-8</code> | 2,582 |
| <code>pop rbp</code> | 1,527 | <code>call; mov</code> | 1,680 | <code>add #I# rsp; pop rbp</code> | 788 | <code>spl=-8</code> | 2,582 |

Table 2: Top five selected features for feature types with feature selection for optimization pass `Early CSE` with a sample set of 2,780 functions, including 1,390 positive samples and 1,390 negative samples. (Sanitized keywords such as `#TARGET#` are abbreviated to only the first letter.)

5 Implementation

We now discuss the implementation details of the various components shown in Figure 1.

Dataset Generation We implemented the dataset generation component in Python. The technique takes a source code repository and compiles it with four levels of optimizations (`-O0`, `-O1`, `-O2`, and `-O3`). During compilation, it extracts the ground truth of optimization passes that modified each function from the compiler log. After compilation, `objdump` is used to disassemble the binary in order to retrieve the instructions of each function. Instructions are sanitized by removing detailed memory addresses, call targets, and immediate values (as discussed in Section 4.1).

We modified the legacy pass manager of the LLVM compiler [11] in order to retrieve the list of optimization passes that modifies a function. We made modifications to the latest development version of LLVM 14 at the time of this writing (commit `#c59ebe4`). We added an option to the existing output flag of LLVM’s legacy pass manager¹ to list the optimization passes that modify a function or components inside a function (e.g., a loop).

Finally, since we use `objdump` to disassemble the compiled binary files into functions, our tool enables debugging symbols during compilation. However, this is not a hard requirement for classification as one could use external tools such as IDA Pro to determine function boundaries of stripped binaries, but prior efforts found little difference in outcome between the two tactics [20].

Dynamic Feature Generation As mentioned in Section 4.2, `PassTell` also supports register values extracted

¹Recent versions of the LLVM compiler contains two pass managers, and by default, the new pass manager is responsible for all optimization passes before code generation. However, the new pass manager does not contain any utility functions to extract the pass names. Therefore, we use the flag `“-flegacy-pass-manager”` to use the legacy pass manager for all passes, including the ones before code generation.

during execution to complement static features. To do this, we make use of Zelos [25], a python-based binary emulator platform that supports x86 (both 32 and 64-bit), ARM and MIPS architecture emulation. Under the hood, Zelos makes use of QEMU CPU emulation and implements system call emulation similar to QEMU usermode, but CPU and syscall-level hooks make comprehensive binary instrumentation readily available. Using this tool, we instrument forced emulation of each function in a binary and record the changes to register values after each instruction within function boundaries. To do so, we extended the emulator to execute a binary, then wait until it has mapped itself in memory and pause execution. Then, for each function, the instruction pointer is adjusted to the function start address before execution resumes. While executing the function, `call` instructions are skipped to ensure that recorded register changes reflect only the target function, while also avoiding recursion and potentially long call chains. Before emulating each function, we map a page of memory and fill it with the start address of the region. The address of this region is used as the return address for the target function as well as for all existing register values that appear to be pointers to memory, to avoid errors related to reading or writing unmapped memory.

Feature Extraction and Classification As discussed in Section 4.3, our approach performs feature selection for each optimization pass. As such, having a dedicated feature extraction component that saves all features to files is highly inefficient. Therefore, we combined the feature extraction phase for both static and dynamic features and the classifier into one classifier component.

We implemented our classifier using Python and the LightGBM library [13]. The classifier iterates through each optimization pass, selecting and extracting features and then creating a `LGBMClassifier`. When training, the classifier first filters the dataset such that the dataset is balanced, with the same amount of positive and negative data. Then, the classifier selects the most popular

features as described in Section 4.3, extracts both static and dynamic features, and trains the `LGBMClassifier`. When classifying, the classifier extracts the static and dynamic features and uses the `LGBMClassifier` to predict whether the function is modified by this optimization pass. After the classifier extracts features and performs classification for all optimization passes, it then merges the results together to generate the final result, the list of optimizations applied to the function.

6 Evaluation

The evaluation includes experiments in two directions. First, we evaluate the effectiveness of our features and our classifier. In this experiment, we compare PassTell with NeuralCI [20], a state-of-the-art approach to compiler configuration identification. To ensure a fair comparison, we first modified our classifier into a multi-class classifier to identify the same compiler configuration as NeuralCI, including the compiler family, the major compiler version, and the optimization level, where each combination is a class. Later, we evaluate our approach in identifying the individual optimization passes. Overall, our experiments seek to answer the following questions:

- RQ1** *How does our approach compare to the state-of-the-art in compiler configuration recovery?*
- RQ2** *Can our approach provide meaningful information regarding feature significance?*
- RQ3** *How well can we infer individual optimization passes?*
- RQ4** *Does the inclusion of dynamic features help with classifying individual passes?*

6.1 Compiler Configuration Identification

We use the same benchmark programs as in NeuralCI [20]. To replicate NeuralCI’s experimental setup, we combine binaries compiled with `-O2` and `-O3` optimization levels into one class, `-OH`. As our prototype utilizes `objdump` to generate the disassembly for each function, we only use the unstripped binaries. Tian et al. [20] observed no difference in classification performance between the stripped and unstripped binaries. Our dataset thus consist of all dynamically linked unstripped executables from the dataset, including `binutils`, `busybox`, `coreutils`, `curl`, `ffmpeg`, `git`, `gsl`, `libpng`, `openssl`, `postgresql`, `sqlite`, `valgrind`, `vim`, `zlib`, and `gdb`.

While inspecting the dataset, we discovered that the dataset is highly unbalanced, with some configurations having significantly less amount of samples than others. We note that this issue is not limited to NeuralCI, as other

Figure 2: Confusion matrix of our LightGBM model applied to the NeuralCI formulation of the compiler classification problem

approaches [2, 15] also do not balance their datasets. To circumvent this issue, we randomly dropped functions from certain configurations to ensure that all configurations have the same number of functions. In the end, our dataset consists of 4,400 functions for each configuration. We split the dataset into an 80% training set and a 20% testing set. Appendix A describes the issue in detail and includes a comparison of the results of NeuralCI before and after balancing the dataset. Finally, NeuralCI includes only unique functions in its dataset, so functions that are identical across configurations are removed. We apply the same procedure.

Since Tian et al. [20] do not include all the code used to construct features from the dataset, we re-implemented the extraction and abstraction of functions. For extraction, we use `objdump` instead of IDA Pro to parse the body of each function. The abstraction for each function is the same as done by Tian et al. [20], namely, mnemonics and register operands are unchanged, base memory addresses in operands are replaced with the symbol `#MEM#`, and immediate values are replaced with the symbol `#IMM#`.

Experiment Results

For the identification of compiler family, compiler version, and optimization level, NeuralCI achieves an average F-1 score of 76.6%, and our approach achieves an average F-1 score of 83.2%. Our re-implementation of NeuralCI produces lower results as reported in their paper [20]. We attribute the variation to be due to the correctly balanced dataset. Overall, the results show that our approach performs better than NeuralCI in identifying the compiler family, the major compiler version, and optimization level.

Interestingly, both the confusion matrix of our ap-

Figure 3: Confusion matrix of NeuralCI in classifying the compiler family, compiler version, and optimization level

proach (Figure 2) and the confusion matrix of NeuralCI (Figure 3) show that identifying the optimization level and the compiler version of binaries compiled with Clang is more challenging. NeuralCI reports similar findings in its evaluation [20]. For functions built by GCC and ICC, both approaches achieve high accuracy in identifying the compiler family, compiler version, and optimization level. For this reason and the fact that we modified the LLVM pass manager to extract pass information, we focus on Clang² for the remaining experiments.

6.2 Optimization Pass Identification

Satisfied with the performance and simplicity offered by PassTell, we focused on tackling the more difficult cases with Clang. Specifically, the compiler pass dataset consists of functions from `binutils` (2.37), `coreutils` (9.0), `httpd` (2.4.51), and `sqlite` (3.36.0) programs compiled with Clang 14, using each of `-O0`, `-O1`, `-O2`, and `-O3` optimization levels, generating a total of 149,814 functions in 552 binaries. Then, we balance the dataset for each pass: for each pass, we randomly select an equal amount of functions with the pass applied (i.e., positive samples) and functions without the pass applied (i.e., negative samples). We also limit the maximum number of samples for each pass to 5,000 positive samples and 5,000 negative samples.

Experiment Results

Overall, our approach achieves an average F-1 score of 92.1%. All but three of the 83 passes have an F-1 score higher than 80%, and the three exceptions all have insufficient amount of samples (<150 functions). If we only con-

²Clang is a front-end of LLVM and is part of the LLVM infrastructure.

sider the 73 passes that contain more than 500 samples, the average F-1 score improves to 93.7%. Table 3 depicts the results of our approach using only static features. For brevity, we only list the detailed results of 13 of the 83 passes in total. We pick these 13 passes because they are optimizations that could affect security [3, 19, 21, 24]: dead store elimination, dead code elimination, code motion, tail call optimization, common subexpression elimination, strength reduction, and peephole optimizations. For these passes, our approach achieves an average F-1 score of 89.8%. The findings further show that, contrary to Pizzolotto and Inoue [15]’s statement, even passes that seem unlikely to be detected, such as dead code elimination, can be identified with high accuracy.

Figure 4: Top 15 Features for Aggressive Dead Code Elimination

To understand why our approach works as well as it does, we inspected the feature significance of some of the security-affecting passes. We choose to inspect the feature significance for Aggressive Dead Code Elimination and Peephole Optimizations because these two passes offer sufficient descriptions about their purposes in the code comment of the LLVM compiler’s source code. Figure 4 shows the top 15 features for the Aggressive Dead Code Elimination pass and the feature type of each feature. The description of the optimization pass in the LLVM compiler’s source code indicates that this pass considers all code to be dead unless proven otherwise and removes all the dead instructions, especially dead code involving loops. The top feature in this case checks whether the function updates the function pointer. Clang omits updating the frame pointer on optimization levels above `-O1`. Similarly, the instruction features `nopl #MEM# %rax $rax #IMM#` and `cs #TARGET#`³ are instructions padding instructions without any semantic meaning whose purpose

³This feature is actually a `nopw` NOP instruction. Due to the different format `objdump` uses for instructions involving the `cs` segment register, this instruction is not parsed correctly. Since segment registers

| Pass | Training Samples | Testing Samples | Precision (%) | Recall (%) | F-1 (%) |
|--|------------------|-----------------|---------------|------------|---------|
| Dead Store Elimination | 1332 | 444 | 86.3 | 85.8 | 85.7 |
| Aggressive Dead Code Elimination | 1092 | 364 | 83.9 | 83.5 | 83.4 |
| Bit-Tracking Dead Code Elimination | 2512 | 838 | 87.6 | 87.5 | 87.5 |
| Remove dead machine instructions | 7500 | 2500 | 88.7 | 88.6 | 88.6 |
| Early Machine Loop Invariant Code Motion | 7500 | 2500 | 93.4 | 93.3 | 93.3 |
| Machine Loop Invariant Code Motion | 739 | 247 | 89.4 | 89.0 | 89.0 |
| Loop Invariant Code Motion | 7500 | 2500 | 90.8 | 90.6 | 90.6 |
| Tail Call Elimination | 88 | 30 | 86.6 | 86.6 | 86.6 |
| Machine Common Subexpression Elimination | 7500 | 2500 | 88.5 | 88.1 | 88.1 |
| Early CSE | 7500 | 2500 | 92.5 | 92.2 | 92.2 |
| Early CSE w/ MemorySSA | 7500 | 2500 | 88.9 | 88.6 | 88.6 |
| Loop Strength Reduction | 7500 | 2500 | 95.4 | 95.4 | 95.4 |
| Peephole Optimizations | 7500 | 2500 | 98.0 | 98.0 | 98.0 |
| Average | | | 90.0 | 89.8 | 89.8 |

Table 3: Precision, recall, and F-1 results on security-related passes when using static features.

is to enforce a 16-byte alignment between functions, and Clang only adds these instructions at `-O1` or above. Since Aggressive Dead Code Elimination is never applied at `-O0`, these three features effectively remove functions with `-O0` optimization level.

Four other features among the top 15 features include various forms of the `cmp` compare instruction, which commonly appears in loops. This finding matches the description of the pass. Finally, some of the top features show significance in the usage of certain registers. Since this pass is applied before register allocation in the compiler pipeline, we speculate that the removal of dead instructions reduces the amount of required registers, causing the register allocator to not use certain registers.

Figure 5: Top 15 Features for Peephole Optimizations

The top features for Peephole Optimizations show similar patterns. Figure 5 shows the top 15 features. The description in the code comments suggests that

are rarely used in 64-bit x86 programs, and we did not find any instructions utilizing that register other than the padding NOP, we conclude that this small implementation quirk does not impact our results.

this pass performs four types of optimizations: optimization of sign/zero extension instructions, optimization of comparison instructions, optimization of loads, and optimization of copies and bitcasts. The top features show that our classifier mainly capture the second type of optimizations that optimizes comparison instructions. Six of the 15 features include a variant of the `cmp` compare instruction; four other features include a jump instruction that usually follows a compare instruction, and one feature includes a `test` instruction, which is functionally similar to a compare instruction. Similar to Aggressive Dead Code Elimination, the top features for Peephole Optimizations also include the feature that saves the frame pointer in order to detect `-O0` functions.

6.3 Case Study on Optimization-induced Vulnerabilities

Although prior studies [3, 19, 21, 22, 24] have shown that compiler optimizations can weaken protections put in place by safe coding practices, it remained unclear whether the nullification of protections could in fact lead to information leakage or other attacks for real-world programs. Thus, we studied three real-world programs and examined how protections introduced by programmers are affected by the dead store elimination optimization: BusyBox (1.35.0), `httpd` (2.4.52), and `crypto++` (5.6.4).

BusyBox BusyBox is a popular embedded program that combines many UNIX utilities into a single binary. Some of the utilities included in BusyBox require password encryption or authentication, such as the `passwd` utility, the `cryptpw` utility, the built-in HTTP server, and the built-in FTP server. Therefore, BusyBox’s codebase includes hashing functions such as MD5 and SHA. When a utility needs to encrypt a password, the utility would call

`pw_encrypt`, which then calls the corresponding MD5, SHA, or DES encryption functions. The SHA encryption function, `sha_crypt`, uses both a local stack object, `L`, and heap objects, `key_data` and `salt_data`, to store intermediate values during the encryption. Listing 1 shows a snippet of this function. Before the function returns, it attempts to erase the three objects using `memset`. However, at `-O3` optimization level, the dead store elimination optimization removes all three calls to `memset`. Thus, the intermediate values remain in the memory after the function returns even though developers took the necessary precautions to erase the data.

```

1 static char * NOINLINE sha_crypt(/*const*/
   char *key_data, /*const*/ char *salt_data)
2 {
3     ...
4     struct {
5         ...
6     } L __attribute__((__aligned__((__alignof__(
       uint64_t)))));
7     ...
8     salt_data = xstrndup(salt_data, salt_len);
9     ...
10    key_data = xstrdup(key_data);
11    ...
12    /* Clear the buffer for the intermediate
       result so that people
13     attaching to processes or reading core
       dumps cannot get any
14     information. */
15    memset(&L, 0, sizeof(L));
16    memset(key_data, 0, key_len);
17    memset(salt_data, 0, salt_len);
18    free(key_data);
19    free(salt_data);
20    ...
21    return result;
22 }

```

Listing 1: Code snippet from the `sha_crypt` function

We tested this program using its `cryptpw` utility that prints the hashed password in the format of Linux's `passwd` format from a given password in plain text. The `cryptpw` utility calls `pw_encrypt` to hash the password text, which calls `sha_crypt` if SHA mode is selected. At `-O0` optimization level, all three objects that contains intermediate values in `sha_crypt` (`L`, `key_data` and `salt_data`) are overwritten to 0 properly at the end of the function. At `-O3` optimization level, however, the entire value of `L` is left on the stack at the end of the function. For the heap objects, the calls to `free` overwrite the first 16 bytes of both `key_data` and `salt_data`. Since `salt_data` is less than 16 bytes, its value cannot be recovered. However, in situations where the input plain text password is longer than 16 characters, the size of `key_data` would be larger than 16 bytes. In this case, part of the intermediate value stored in `key_data` would persist in the heap memory after its scope. After `sha_crypt` returns, `pw_encrypt` then calls a simple clean up func-

tion and returns to the caller utility. At this point, both the stack object `L` and the partial leftover from the heap object `key_data` still exist in the memory without being overwritten. This means that if an attacker finds a memory disclosure vulnerability in the caller utility of `BusyBox` before the intermediate values are eventually overwritten by subsequent functions, then the attacker can recover the entire value of `L` and/or the value of `key_data` after the first 16 bytes. Since `BusyBox` includes an HTTP server and an FTP server that both use `pw_encrypt`, it would be possible for an attacker to launch an attack remotely.

We have submitted a bug report for this issue ⁴.

```

1 int get_password(struct passwd_ctx *ctx)
2 {
3     char buf[MAX_STRING_LEN + 1];
4     ...
5     else {
6         ...
7         apr_password_get("Re-type new password
           : ", buf, &bufsize);
8         if (strcmp(ctx->passwd, buf) != 0) {
9             ctx->errstr = "password
               verification error";
10            memset(ctx->passwd, '\0', strlen(
                ctx->passwd));
11            memset(buf, '\0', sizeof(buf));
12            return ERR_PWMMISMATCH;
13        }
14    }
15    memset(buf, '\0', sizeof(buf));
16    return 0;
17    ...
18 }

```

Listing 2: Code snippet from the `get_password` function

Httpd and Crypto++ The HTTP server `httpd` contains a support utility program, `htpasswd`, that manages the files that store usernames and passwords. This program includes a function `get_password()` that reads the password entered by the user to a local buffer, and stores the buffer to a `passwd_ctx` struct. Before it returns, the function calls `memset` to erase the buffer such that the password entered by the user would not stay in the memory. Listing 2 shows a snippet of this function. Before any return statement, the function erases the memory of the buffer, `buf`, that contains the user-entered password at line 11 and line 15 in Listing 2. However, at `-O3` optimization level, the dead store elimination optimization removes the function call to `memset` that erases `buf`, causing the password in plain text to persist in the stack memory after `get_password()` returns, contrary to the developers' intention.

We tested this program and discovered that immediately after the function returns, we could recover the exact password in plain text in the stack memory. It is

⁴https://bugs.busybox.net/show_bug.cgi?id=14806

worth noting that after `get_password` returns to its caller, `mkehash`, the caller later calls other functions, overwriting the stack memory that contains the password as the stack frame of `get_password` is smaller than the stack frame of subsequent functions. Therefore, if an attacker finds a memory disclosure vulnerability in `mkehash` between the call to `get_password` and the subsequent function call, then they can retrieve the password in plain text.

`Crypto++`, a cryptography library written in C++, contains a similar issue as `htpasswd`. The function `CAST256::Base::UncheckedSetKey` uses a call to `memset` to erase its local variable, `kappa`, which holds the hashed key. At `-O3` optimization, the dead store elimination optimization removes this call, causing the secret key to remain in stack memory after the function returns.

For validation purposes, we use the entire compiler pass dataset (discussed in Section 6.2) as our training set for `BusyBox` and `crypto++`. For `httpd`, our compiler pass dataset also contains `httpd`, albeit a different minor version, so we exclude all functions in `httpd` from our training set. Our classifier correctly identifies the `Dead Store Elimination` pass for all three functions at `-O3` optimization level. At `-O0`, the classifier mis-identifies `sha_crypt` for `BusyBox` but identifies the missing of the pass correctly for `httpd` and `crypto++`.

6.4 The Effects of the Dynamic Features

Finally, we evaluate the value of including dynamic features. For that, we use the same dataset as in Section 6.2, but apply additional filtering. Specifically, because our current implementation of our dynamic feature generator is unable to generate register features for all functions in the dataset, we filter the dataset to only include functions that our generator achieved a minimum coverage threshold. Additionally, we only include passes that were applied to more than 500 functions. Since our goal is to evaluate the effects of the dynamic features and not the coverage of the feature generator itself, we view this as a reasonable way to understand what impact dynamic features could have on classification performance.

To compare to the baseline, we ran our approach using both static features and dynamic features. For the latter, we experimented with coverage thresholds ranging from 30% to 60%. For these configurations, we used the same filtered dataset and artificially removed dynamic features to reach the target coverage.

Experiment Results

Table 4 depicts the results. We only show cases where the difference in F-1 score is greater than 1%. While the average F-1 score appears similar regardless of the inclusion of dynamic features, the detailed results tell a more

compelling story. Some passes, such as `Remove dead machine instructions`, show a notable decrease in F-1 score, while others (e.g., `Early CSE w/ MemorySSA`) improve by almost 4.0%.

Figure 6: Top 15 Features for Early CSE w/ MemorySSA with both static and dynamic features

To better understand the reasons, we examined the most important features as deemed by the `LGBMClassifier` classifier. Figure 6 shows the top 15 features and the significance of each feature for the `Early CSE w/ MemorySSA` pass. The description of this pass indicates that this pass removes “trivially redundant instructions”. The top 15 features include three dynamic features: `eip=7`, `flags=64`, and `flags=4`. The EIP register is the instruction pointer, and the delta of this register shows information of instruction size, which is not available in the static features. Similarly, the `FLAGS` register, as partial alias of the `EFLAGS` register, contains various processor flags that are implicitly set during arithmetic operations and interrupts. Since this register is only set implicitly as a side effect of instructions, static approaches cannot extract this information by analyzing the disassembly or the binary code.

An examination of the `Rotate Loops` pass yields similar insights. Here, the top 15 features (Figure 7) include two dynamic features: `flags=-68` and `eip=10`. These results indicate that dynamic features, instruction pointer and processor flags in particular, can provide useful information in the detection of some optimization passes.

Lastly, we noticed that as we varied the coverage threshold, a few passes showed a noticeable improvement in F-1 score at higher coverage levels. For these passes, the result appears to be related to the number of dynamic features and their significance. For example, for `Early CSE w/ MemorySSA`, at 30% coverage, the top 25

| Pass | Training Samples | Testing Samples | Static Only (%) | Static & Dynamic (%) |
|---|------------------|-----------------|-----------------|----------------------|
| Early CSE w/ MemorySSA | 607 | 203 | 82.2 | 86.1 |
| Rotate Loops | 400 | 134 | 84.2 | 86.5 |
| Merge disjoint stack slots | 598 | 200 | 94.4 | 96.5 |
| Control Flow Optimizer | 2,200 | 734 | 95.6 | 97.1 |
| Canonicalize natural loops | 396 | 132 | 87.9 | 89.4 |
| Peephole Optimizations | 1,297 | 433 | 94.9 | 96.3 |
| Two-Address instruction pass | 3,454 | 1,152 | 94.9 | 96.0 |
| Remove Redundant DEBUG_VALUE analysis | 1,515 | 505 | 88.1 | 87.1 |
| PostRA Machine Sink | 634 | 212 | 90.1 | 89.1 |
| Live DEBUG_VALUE analysis | 3,030 | 1,010 | 97.4 | 95.9 |
| Machine Instruction Scheduler | 1,303 | 435 | 93.3 | 91.2 |
| Simplify the CFG | 1,912 | 638 | 91.2 | 89.0 |
| Remove dead machine instructions | 903 | 301 | 91.0 | 86.7 |
| Average for All Passes with at Least 500 Samples | | | 92.9 | 93.0 |

Table 4: F-1 scores using only static versus static and dynamic features. The table list only results where the difference of F-1 score is $\geq 1\%$. The coverage threshold is set to $\geq 70\%$. Security-related passes are highlighted in dark grey.

Figure 7: Top 15 Features for Rotate Loops with both static and dynamic features

features include four dynamic features, and at 70% or higher, the top 25 features include eight dynamic features. We posit that future improvements in the way dynamic features are collected could boost the classification for more passes, without negatively impacting others.

7 Limitations

Our implementation of the data collection component only records optimization passes applied to functions or components within a function (e.g., loops and basic blocks). Optimization passes applied to larger units such as modules and call graphs are not studied. Therefore, our analysis does not cover cross-function optimizations such as the function inlining. This limitation stems from the fact that the LLVM compiler does not report the specific

functions modified by a module pass or call graph pass. Similarly, our data collection component does not support extracting whole-program optimizations applied at link time, which could also negatively impact security [21].

In addition, our approach targets only binary files directly generated by the compiler. Thus, it can not be used in situations where the binaries are modified after compilation, such as obfuscated binaries or binaries with binary patches applied. This limitation is not unique to us.

8 Conclusion

We presented a light-weighted approach to the problem of compiler configuration identification. Our approach combines a novel technique for feature extraction and a scalable classifier for performing compiler provenance recovery. To further improve the accuracy of our classifier, we explored the use of dynamic features extracted by force-executing functions using a binary emulator. Overall, our approach shows comparable results as the state-of-the-art in the original problem of identifying the compiler family, the compiler version, and the optimization level, and pushes the field forward by showing that one can even identify individual optimization passes.

9 Availability

Our coarse-grained compiler configuration classifier and our fine-grained compiler pass classifier are available at <https://github.com/zeropointdynamics/passtell>. The balanced compiler configuration dataset (§6.1), the compiler pass dataset (§6.2), and the compiler pass dataset with high dynamic feature coverage (§6.4) are also available. Furthermore, Zelos, our binary emulator we use to generate dynamic features, is open sourced [25].

A The Unbalanced Dataset

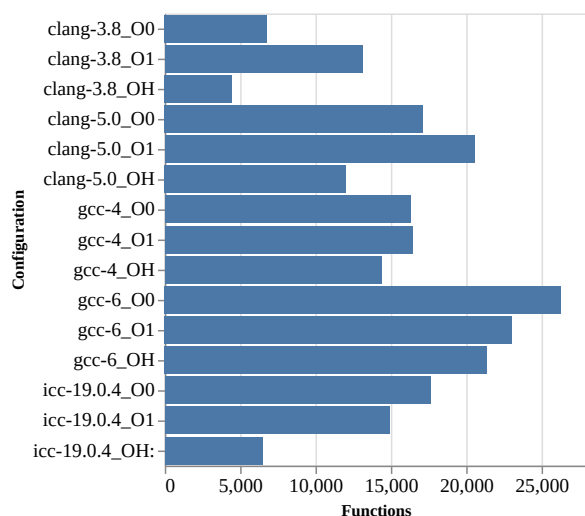

Figure 8: The distribution of samples in compiler configurations in the NeuralCI dataset (prior to re-balancing).

Figure 8 shows the number of functions for each configuration in the original dataset of NeuralCI [20], for 64-bit dynamically linked and unstripped executables. Some configurations, such as Clang 3.8 at `-OH` optimization level, contain significantly less functions than others. This unbalanced dataset could potentially cause bias in evaluation. Therefore, we balanced this dataset by randomly removing functions such that all configurations have the same amount of functions (see Section 6.1).

| Dataset | Precision | Recall | F-1 |
|-------------------|-----------|--------|-------|
| Unbalanced | 83.5% | 83.5% | 83.5% |
| Balanced | 76.6% | 76.6% | 76.6% |

Table 5: Comparison of NeuralCI results using the unbalanced dataset and the balanced dataset

To replicate the evaluation of NeuralCI as accurately as possible, we ran an additional experiment using Neu-

Figure 9: Confusion matrix of NeuralCI using the unbalanced dataset

ralCI with the unbalanced dataset. Table 5 shows the results of NeuralCI using the unbalanced dataset and the dataset after we balanced the data size. The results using the unbalanced dataset show roughly the same results as reported by Tian et al. [20], with a negligible variation (<1%). Notice, however, that after balancing the dataset, NeuralCI’s performance declines. Compared to the confusion matrix of NeuralCI using our balanced dataset (Figure 3), the confusion matrix of NeuralCI using the unbalanced dataset (Figure 8) shows drastically better results for identifying the GCC version at `-OO` optimization level, likely because GCC 6 has significantly more samples than GCC 4 at `-OO` optimization level. Likewise, the results for Clang functions also differ.

B Artifact Appendix

Abstract

Our artifacts include the dataset for our experiment in Section 6.1, 6.2 and 6.4, our coarse-grained compiler configuration classifier for Section 6.1, and our fine-grained compiler pass classifier for Section 6.2 and Section 6.4. Our artifacts require a Linux machine (or Windows Subsystem for Linux) with 32GB of RAM and 16GB of storage. Since our classifiers use only shallow learning, a discrete GPU is not required. On our machine with an AMD Ryzen 7 3700X processor, the coarse-grained classifier requires about two hours to finish, and the fine-grained classifier takes about an hour.

Scope

The artifacts allow reproducing our quantitative experiments in Section 6, including coarse-grained compiler configuration identification (Section 6.1), optimization pass identification using only static features (Section 6.2),

and optimization pass identification using both static and dynamic features (Section 6.4).

Contents

Our artifacts include the following contents:

1. `balanced_dataset.csv`: The dataset for coarse-grained compiler configuration classification. As discussed in Section 6.1, this dataset is a balanced subset of the dataset used in NeuralCI [20].
2. `config_classifier.py`: The coarse-grained compiler configuration classifier.
3. `data.csv`: The dataset for fine-grained compiler pass classification used in Section 6.2.
4. `data_dynamic.csv`: The dataset for dynamic feature evaluation used in Section 6.4. As discussed in Section 6.4, this dataset is a subset of `data.csv` that only includes functions whose dynamic feature coverage are at least 70%.
5. `LICENSE`: The license of our artifacts.
6. `passtell.py`: The fine-grained compiler pass classifier.
7. `README.md`: Installation and running instructions.
8. `requirements.txt`: List of required Python libraries.
9. `static_opcode_features.py`: Library module required for `passtell.py`.

Hosting

The classifiers and the datasets are available at <https://github.com/zeropointdynamics/passtell> in the main branch with commit ID 0c88e8d.

Requirements

Our classifiers have the following requirements:

1. A 64-bit Linux machine with at least 32GB of RAM and 16GB of storage. We have tested our artifacts on Arch Linux (rolling release, updated in May 2022) and Ubuntu 20.04 (Windows Subsystem for Linux).
2. Python 3. For Ubuntu and other Linux distributions that do not have a default `python` command, setting the symbolic link from `python` to `python3` is required. On Ubuntu, this can be done by installing the `python-is-python3` package.
3. Graphviz.
4. Python libraries listed in `requirements.txt`.

JITServer: Disaggregated Caching JIT Compiler for the JVM in the Cloud

Alexey Khrabrov
University of Toronto

IBM

Vijay Sundareshan
IBM

Eyal de Lara
University of Toronto

Abstract

Managed runtimes such as the Java virtual machine (JVM) rely on just-in-time (JIT) compilers to improve application performance by converting bytecodes into optimized machine code. Unfortunately, JIT compilation introduces significant CPU and memory runtime overheads. JIT compiler disaggregation is a technique that decouples the JIT from the JVM and ships compilation to a separate remote process. JIT disaggregation reduces overall memory usage; however, its communication overheads result in higher system-wide CPU usage.

JITServer is a disaggregated caching JIT compiler we implemented in the Eclipse OpenJ9 JVM. It improves system-wide resource utilization by enabling the caching of compiled native code and its reuse in JVMs running on different machines. JITServer is transparent to the application developer, and supports all the dynamic features in the JVM specification. In our experiments, JITServer reduced overall CPU cost by up to 77%, overall memory usage by up to 62%, application start time by up to 58% and warm-up time by up to 87%.

1 Introduction

Java virtual machines (JVMs) rely on just-in-time (JIT) compilers to improve the performance of Java applications by converting the bytecodes of the application into optimized machine code. Since this transformation is done at runtime, the JIT has the ability to tailor-fit the generated code for a specific application instance and its execution environment. On the downside, JIT compilation can introduce significant runtime overheads in terms of processing power and memory. The extra CPU cycles needed for compilation can interfere with applications' progress, delaying their start-up, increasing their warm-up time or affecting the response time and quality of service. Similarly, the data structures allocated by the JIT compiler create unpredictable spikes in memory usage, which increase memory footprint and can lead to performance degradations (due to paging) and out-of-memory failures. In our experiments, JIT compilation accounted for up to 50% of CPU time used during the start-up and warm-up phases, and for up to hundreds of MBs of memory footprint.

The competition for resources between the application and the JIT is more intense in CPU and memory constrained environments such as containers and VMs found in cloud datacenters that maximize resource utilization and application density.

Automatic scaling of cloud applications is done by launching and shutting down instances based on load. Frequent restarts of applications pose serious challenges to Java workloads due to the high start-up overhead of JIT compilation, which needs to be amortized over a long execution period. The memory overhead of JIT compilation is more significant for smaller (in terms of overall memory usage) application instances which are common in the cloud (e.g. microservices).

JIT compiler disaggregation is a technique that addresses these overheads by decoupling the JIT from the JVM and running it in a separate remote process. The JIT no longer steals CPU cycles from the application, which leads to more predictable behavior and better quality of service, and improves application warm-up in CPU constrained environments. Memory footprint spikes are also eliminated, enabling smaller containers, higher application density, and reduced costs in the cloud. Moreover, remote JIT simplifies resource provisioning: the user only has to consider CPU and memory required for application execution, while compilation resources can be scaled independently of the applications.

While JIT disaggregation reduces overall memory usage, on the downside, it can result in higher system-wide CPU usage. The CPU cost and latency of each compilation in this setting is higher compared to local JIT due to communication overheads. JIT overheads are not eliminated, but rather transferred to a different host, at the expense of additional networking and serialization costs.

We argue that in order to achieve the full benefits of disaggregated JIT, the compiler server resources must be effectively shared between multiple client JVMs by making it possible to reuse compilations of common methods. Unfortunately, reusing dynamically compiled native code across multiple JVM instances is a challenging task. JIT-compiled code cannot be simply plugged into a different JVM in the general case since it often contains pointers to runtime entities that are located at different addresses in different JVMs, and relies on runtime assumptions that might not hold in a different JVM environment. Due to the dynamic nature of the JVM, locating runtime entities and verifying assumptions across JVM processes is more difficult compared to relocating statically-compiled code in languages like C. The key idea is to use secure hashes of immutable class metadata to efficiently detect equivalent classes and methods across JVMs.

In this paper, we describe the design and implementation

of JITServer - our disaggregated JIT compiler in Eclipse OpenJ9 [6], a popular open source JVM. JITServer caches compiled native bodies and reuses them for future compilation requests for the same methods from other client JVMs. This enhancement dramatically decreases compilation latency for cache hits and significantly reduces overall resource usage by amortizing compilation costs over multiple clients. Caching compiled code at the server happens transparently and does not add any complexity to application development. Our main use case is running multiple application instances in a cloud datacenter in, e.g., containers with resource limits. Remote JIT might not be beneficial if the JVM has plenty of resources for local JIT, or if the network latency is high.

This paper makes the following contributions:

- We propose a novel mechanism that facilitates caching of compiled native code in a remote JIT compilation system and enables correct, transparent and efficient reuse of such code by JVMs running on different machines. We show that caching is necessary to achieve the full benefits of JIT compiler disaggregation.
- We describe the design and implementation of JITServer. Unlike previous work, our solution is compliant with the JVM specification, does not rely on simplifying assumptions, and is implemented in a production grade JVM with a sophisticated JIT. We provide insight into the challenges of implementing remote JIT in a dynamic environment such as the JVM and the ways to solve them.
- We present the first (to the best of our knowledge) study of remote JIT in the context of cloud computing. We show that JITServer improves start time, warm-up time, CPU and memory usage, without trading-off peak throughput, allowing more efficient, higher density deployments of JVM-based applications in the cloud. In our experiments, JITServer reduced overall CPU cost by up to 77%, overall memory usage by up to 62%, application start time by up to 57% and warm-up time by up to 87%.

The rest of the paper is organized as follows: Section 2 provides a survey of related work and motivates our solution; Section 3 presents the design of JITServer and its novel mechanism for reusing compiled code in multiple JVMs; Section 4 evaluates the performance of our system; finally, Section 5 concludes the paper and explores future work directions.

2 Motivation and Related Work

In this section we present a survey of existing solutions for the JIT overhead problem and discuss their limitations.

2.1 Static AOT Compilation in the JVM

One way to circumvent the negative effects of JIT compilation is to use static ahead-of-time (AOT) compilation. HotSpot JVM used to include a (now deprecated [10]) static AOT compiler `jaotc` [9] that compiled the bytecode of an explicitly specified list of Java classes or `.jar` files into native code.

GraalVM Native Image [7] compiles a Java application including all the classes it uses (determined by static analysis) into a standalone native executable, and can run parts of the application initialization code at AOT compile time [31].

However, an inherent limitation of static AOT compilation is the *closed world assumption*: all the code that can execute at runtime must be available at compile time. This assumption severely limits support for dynamic JVM features such as custom dynamic class loading, class definition and redefinition at runtime, and `invokedynamic` bytecodes. Static AOT only supports a subset of Java and JVM bytecodes.

On the performance front, static AOT compilers typically do not take advantage of the latest CPU features, because the code they produce must be compatible with a wide range of target machines. Moreover, the lack of runtime profiling information can lead to suboptimal performance. While it is possible to use profiling information at build time, it requires a realistic workload, which makes application development more difficult. In addition, performance profile of a given method can change between application phases, and achieving peak performance in such cases still requires dynamic recompilation at runtime.

2.2 Sharing Compiled Code between JVMs

JIT overhead can be reduced by caching and sharing compiled code among JVMs. Examples include ShMVM [20] (based on HotSpot), ShareJIT [32] (based on Android Runtime), and the Shared Classes Cache (SCC) [16, 19] and dynamic AOT compilation in OpenJ9. We focus on the latter as the more recent and practical implementation of this approach.

SCC in OpenJ9 is a memory mapped file used to cache compiled code and the internal representation of immutable class metadata. The SCC is populated in a *cold* run and is subsequently consumed by other JVM instances in *warm* runs. The SCC improves start-up and warm-up performance in the warm runs since the class metadata is already available in a pre-processed format and does not need to be parsed from the class files, and loading cached compiled methods is much less CPU-intensive than JIT-compiling them. This approach is called *dynamic AOT compilation*: methods are compiled and stored in the SCC during execution, in contrast with static AOT where the code is compiled before it runs.

Unfortunately, this approach does not completely eliminate the need for a JIT compiler for two reasons: (i) the hit rate in the SCC is not 100% as the set of compiled methods can vary from run to run; and (ii) dynamic AOT code can be slower than regular JIT-compiled code since it has to meet certain constraints in order to be relocatable and usable in a different JVM instance. Therefore, performance critical methods are still JIT-recompiled with more optimizations in order to achieve peak throughput. Since such compilations are responsible for most of the JIT memory overhead, this approach cannot effectively reduce peak memory usage.

While it is possible to ship a pre-populated SCC with an ap-

plication, the complexities involved often make it impractical. The associated increase in image size can be significant up to hundreds of MBs (63-128% increase for the applications we used in our evaluation). A larger image size adds overhead on the critical path of deployment and contributes to the cold start latency. Dynamic AOT code makes assumptions about the execution environment such as target CPU instruction set, GC algorithm (its reference read and write barriers), and heap size (determines compressed pointer shift). Shipping a pre-populated SCC requires either maintaining multiple versions for all possible combinations of CPU generations and JVM parameters (which complicates deployment), or generating suboptimal portable code that works across all configurations.

Managing the pre-populated SCC puts additional burden on application developers and increases complexity and cost of continuous integration and deployment. Caching methods compiled during warm-up requires simulating a realistic workload, which can be a complex task. Creating a fully populated SCC can also increase application build times by up to orders of magnitude since it can take minutes of application run time to achieve full warm-up. Anecdotal evidence (e.g. Docker images for OpenJ9 [2] and Open Liberty [11] - a popular Java framework optimized for OpenJ9, and the Java runtime in the OpenWhisk [4] serverless platform) suggests that in practice, the SCC is typically pre-populated only by starting up and shutting down an application instance, and does not include any methods compiled during the warm-up phase.

Another way to leverage the SCC is to share it locally between JVMs on a given host, populating it dynamically at runtime instead of pre-populating it at application build time. However, this approach also has drawbacks. Sharing the SCC between applications creates the potential for side-channel attacks and other security issues. Thus if sharing is limited to a single application, the scheduler is forced to pack instances of the same application on the same host, which can lead to “hot spots” during load spikes when multiple instances of the same application contend for (often oversubscribed) resources. This approach also increases applications’ exposure to individual host failures. Managing per-application SCC volumes shared between containers also complicates deployment.

2.3 Checkpointing and Reusing JVM Processes

Another approach to circumvent JVM slow start is to checkpoint the state of a “warm” JVM process and restore it when starting a new application instance. Cloneable JVM [24], ReplayableJVM [30], and Catalyzer [22] explored checkpointing well-defined and deterministic state after the start-up phase of the application. Such snapshots do not include any methods compiled during warm-up under load, and still require JIT compilation to reach peak performance. Checkpointing also suffers from the same usability issues as shipping a pre-populated cache of compiled methods: additional developer effort and having to generate slower portable code or maintain multiple versions for different CPUs and JVM configurations.

HotTub [27] takes a somewhat different approach of reusing JVM processes to keep the JVM state “warm” for the next run of the same or similar application. Photons [23] co-locates multiple copies of a serverless function as threads within the same JVM instance. These systems only reuse compiled code within the same machine, and can only persist it across non-concurrent invocations by keeping the pre-warmed JVMs running, which incurs a significant idle footprint.

2.4 Remote JIT Compilation

Remote JIT has been originally proposed in research that focused on embedded, mobile, and IoT devices where local JIT is prohibitively expensive in terms of memory, CPU or energy consumption [17, 18, 21, 25, 28, 29]. JCOD [21], MoJo [28] and VM* [25] are based on simplified JVMs and JIT compilers that either do not rely on dynamic JVM runtime information, or only support static AOT compilation of a subset of Java.

Lee et al. [26] describe a JIT compilation server based on Jikes RVM, a research JVM written in Java. To the best of our knowledge, their work is the state-of-the-art in the literature on remote JIT for the JVM. Its design assumes that all the information needed to compile a method is included in the compilation request, which becomes impractical in a complex modern JIT. The authors do not consider overall resource usage (including the server), and only use simulations to evaluate performance with multiple clients.

Foremost, these previous approaches do not reduce, and in fact can increase, system-wide CPU usage. Each individual remote compilation consumes more CPU time than its local equivalent (assuming homogeneous hardware) due to communication overheads, and takes more time overall due to network latency. As we show in our evaluation (see Section 4.2), remote JIT can increase overall CPU usage, especially for short-running workloads that are common in modern cloud computing. In this paper, we leverage caching compiled methods at the server to reduce the overall CPU cost by amortizing it over multiple clients. In addition, we show that for cloud workloads, JITServer significantly reduces overall memory consumption since the spikes of maximum memory usage from multiple clients are unlikely to align.

Azul Cloud Native Compiler [5] is a recently released remote JIT for the Azul JVM. Unfortunately, there is only limited technical information available about the design of this proprietary closed-source system. In particular, it is not known if it implements caching, or how it affects system-wide resource usage. We are unable to compare performance against it since its license forbids publishing benchmarking results.

Remote JIT is less susceptible to failures than other disaggregated designs (e.g. memory disaggregation) since it has no shared hard state. Unlike the case of mobile and IoT devices (the main target of previous remote JIT work), network latencies in cloud datacenters are relatively low, and our evaluation shows that remote JIT performs very well in this setting. Modern cloud applications themselves are also typically dis-

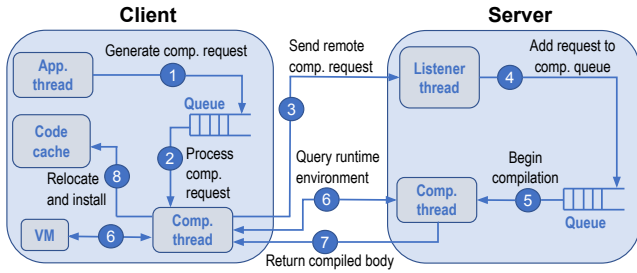

Figure 1: Remote compilation mechanism

tributed, thus remote JIT does not exacerbate the reliability and latency concerns. Remote JIT shifts resource provisioning complexity from the application to the infrastructure, which can be arguably beneficial. Local JIT requires application developers to manage the complexity and extra costs of over-provisioning memory (which goes unused after warm-up) and CPU (to maintain QoS despite JIT activity during warm-up) for each JVM. Instead, the operator’s effort to setup JITServer autoscaling can be reused many times across applications.

3 Design and Implementation

In this section we present an overview of JITServer design and implementation. We start with the description of the remote compilation mechanism, and then explain how we enable caching compiled methods to be reused by multiple clients.

3.1 Remote Compilation Mechanism

Figure 1 shows the high-level design of remote compilation in JITServer. The *client* on the left is a complete JVM running an application, while the *server* on the right is a separate, possibly remote process offering a JIT compilation service shared by multiple client JVMs connected to it. In this paper, we focus on the mechanisms. We plan to explore automatic sizing and scaling of JITServer resources in future work.

Existing remote JIT designs assume that each compilation is a simple request-reply operation that requires a single network round-trip since all the data required by the server is either already available there or included with the request [26]. While this was feasible for simple JIT compilers in previous work, such a design proved difficult to implement in a modern JVM. The JIT in OpenJ9 has over 100 optimization passes that use over 100 types of JVM state queries, compared to ~40 optimizations and 12 types of state in [26]. We took a different approach that resulted in lower implementation effort and complexity: a compilation request only carries data that is likely to be used by most compilations, and remaining data is requested from the client on demand, cached at the server, and invalidated when necessary to ensure correctness.

OpenJ9 runs a number of background threads that perform JIT compilation concurrently with application threads. It uses *tiered* compilation: methods are scheduled for compilation at lower optimization levels once they reach certain invoca-

tion thresholds, and particularly hot methods that consume a significant portion of CPU time are scheduled for recompilation at higher optimization levels. The bytecode interpreter and the sampling thread add compilation requests to a queue consumed by the compilation threads. The number of active threads is adjusted dynamically: additional ones are activated when the JIT is starved of CPU time (e.g. if there is a large number of application threads) or the queue becomes too large. Compilation threads compile one method at a time, and each compilation is a single-threaded task.

JITServer uses the same basic design with compilation queues and threads on both the client and the server. At Step 1, application threads add requests to the compilation queue. At Step 2, a client compilation thread dequeues a request and sends a remote compilation request to the server (Step 3). The client sends enough data for the server to start the compilation, such as the bytecodes of the method. A listener thread on the server accepts the connection and enqueues a compilation request (Step 4), and a compilation thread reads the request data from the network and starts the compilation (Step 5).

During remote compilation, the server may issue various queries to the client requesting information about classes, methods, fields, execution environment, etc. (Step 6). When the compilation is complete, the server sends the compiled body to the client (Step 7) along with metadata that needs to be instantiated at the client. The client performs necessary relocations (e.g. fixes up calls to runtime helper methods) and installs the compiled method in its own code cache (Step 8) - now it is ready to be executed. As long as the compilation queue is not empty, the client thread keeps the connection open and reuses it for subsequent requests.

Each compilation is performed by a dedicated pair of threads - one on the server and one on the client. The number of in-progress compilations is limited by the maximum number of client threads (16 in the current implementation). Our evaluation shows that this value works well in practice. We used a maximum of 128 server threads in our experiments.

The server JIT compiler in our current implementation is identical to the local OpenJ9 JIT compiler and uses the same set of optimizations and heuristics that control its behaviour. All compilations are performed remotely. We focus on evaluating the benefits of JIT disaggregation and caching on their own in this paper, and plan to explore how the compiler can be improved in the disaggregated setting in our future work.

3.2 Caching JVM Runtime Information

Remote compilation of large or complex methods can require exchanging a large number of messages between the client and the server. To reduce the negative effect of network latency on performance, the server aggressively caches runtime information received from the clients. Note that this is different from caching the resulting compiled code, which we describe in Section 3.4. Caching is essential for performance: in an early JITServer prototype that did not implement such

caching, client threads alone used ~10x more CPU time than local JIT. Caching reduced the average number of messages per compilation from over 1000 to ~40.

The server handles requests from multiple clients in parallel and maintains their data in *client sessions* identified by a unique client ID included with each compilation request. A session is created when a client first connects to the server, and destroyed when the client terminates or stays inactive for a long time. Most of the information that does not change throughout the client's lifetime (e.g. JVM configuration and class metadata for primitive types) is sent with the first compilation request. Mutable client state needs to be synchronized with the server as classes are being loaded, unloaded, or redefined, and profiling information is updated. We describe how we handle caching of important types of client data.

Class Metadata Java classes are represented in OpenJ9 as data structures called ROMClasses, which represent immutable data, including method bytecodes, and RAMClasses, which contain the mutable data and point to the ROMClasses they are based on. Multiple RAMClasses can use the same ROMClass, e.g. if they are loaded by different class loaders.

The server maintains mirrors of the clients' ROMClasses and RAMClasses. To reduce memory consumption, it stores a single copy of each unique ROMClass that is shared by all the clients using it. To handle class unloading and redefinition, the client sends with each compilation request the list of classes unloaded or redefined since the previous compilation request, which are in turn deleted from the server cache.

Server compilation threads are synchronized with class unloading and redefinition using a reader-writer lock. Threads acquire this lock for writing before deleting the entries, and acquire it for reading while performing a compilation. When runtime information queries are sent to the client, the lock is released, and the client's reply will also indicate whether class unloading happened during this compilation, in which case the compilation is aborted and retried.

Class Hierarchy Table CHTable (class hierarchy table) is an OpenJ9 data structure that captures relationships between classes and enables fast discovery of such relationships used for speculative optimizations, e.g. devirtualization. The server mirrors the client's CHTable and keeps it up to date with incremental updates sent along with the compilation requests.

To guarantee functional correctness, the server must process class unloading/redefinition and CHTable updates in the same order as the client. This requirement imposes a partial order on compilation requests: *critical* requests that carry updates must be processed in the same order as they originated at the client, while other *non-critical* requests between subsequent critical requests can be reordered. We use a sequencing scheme to order critical requests: if the server receives an update with an out-of-order sequence number, it suspends the compilation thread until the update with the expected sequence number arrives. If the expected message is lost, after a timeout, the server clears cached data for the client and restarts

the update mechanism by requesting the entire CHTable.

Profiling Data While interpreting Java methods, OpenJ9 collects profiling data about branch direction and targets of virtual and interface calls and `instanceof/checkcast` operations. The optimizer at the server makes extensive use of this data and issues many queries to the client. To reduce the number of messages, we batch profiling data requests by sending the data for all the bytecodes in the method in a single reply.

Unlike class hierarchy information, imprecise profiling data does not affect functional correctness of generated code. Profiling data for already compiled methods (which can be inlined into newly compiled ones) has stabilized and can be cached without significant effect on performance. In contrast, profiling data for interpreted methods continue to be accumulated, and using a stale version can lead to bad optimization decisions. Thus, the server caches this data only for the duration of the current compilation.

3.3 Reliability and Security

The client JVM in our design still includes a fully functional local JIT compiler. Out-of-process compilation makes Java applications more resilient to JVM crashes caused by intermittent software bugs in the JIT compiler. JITServer only maintains soft state, allowing transparent failure handling: after a server crash, the client JVM can switch to a different JITServer instance or compile the method locally (which is unlikely to trigger the same bug again) and continue execution, and the failed JITServer instance can be simply restarted.

We assume a security model where the server instance and all the client JVMs that connect to it are in the same security domain: the clients need to trust the server to generate correct native code. JITServer supports encrypted communication using OpenSSL. Encryption adds a relatively small but non-negligible overhead: it increases start time by up to 9%, warm-up time (to 90% of peak throughput) by up to 5%, and CPU time used by the JIT by up to 5%. Unencrypted communication can be used in settings with an isolated network (e.g. on-premises cloud deployments) to reduce the overhead.

Even if communication is encrypted, remote JIT can potentially introduce side channels for an in-network attacker that can observe the timing and sizes of messages exchanged between the server and the client JVMs. However, the same issue applies to any distributed or client-server application, and in practice does not prevent their widespread adoption.

3.4 Reusing Dynamically Compiled Code

OpenJ9 is capable of producing relocatable code (aka dynamic AOT code) that can be reused in a different JVM instance running on the same machine. It maintains a Shared Classes Cache (SCC) - a memory-mapped file shared by JVMs on the same host that stores immutable class metadata and dynamic AOT code. These cached methods include additional metadata that is used to locate and patch pointers to JVM runtime entities such as RAMClasses (see Section 3.2)

residing at different addresses in different JVMs, and to verify that assumptions (e.g. about class hierarchies) made during compilation still hold in a different JVM environment.

Dynamic AOT methods refer to SCC entities in their *validation and relocation records* by offset within the SCC. While this approach is very efficient when running on a single machine, this means that dynamic AOT code cannot be reused as-is on a different machine (with a different SCC). Since the order of class loading and dynamic AOT compilations is not deterministic, SCC entities will generally reside at different SCC offsets on another machine, making dynamic AOT code generated on another machine invalid. The fundamental source of this problem is the tight coupling of the dynamic AOT code with the SCC it is stored in. We propose a new scheme to store these artifacts independently.

Our caching mechanism is based on the existing OpenJ9 infrastructure for relocating dynamically compiled code, but uses a different way of identifying runtime entities such as classes across JVMs. Our novel scheme allows us to decouple compiled code from class metadata and enable its reuse in any JVM running on any host. We store compiled methods in a *serialized* format that refers to JVM runtime entities by globally unique identifiers instead of SCC offsets. When another client JVM requests a compilation of the same method, the server replies with a cached serialized version. The client then *deserializes* the method by finding the corresponding runtime entities, and then relocates and loads the native code.

Some compilations (e.g. hot methods at higher optimization levels) do not use the relocatable format in order to maximize the performance of generated code, since relocation limits optimization opportunities. The resulting hit rate in the JIT-Server cache is 85-93% during the start phase and 68-76% during warm-up in our experiments, depending on the application. In our future work, we will explore compiling more methods as relocatable code to increase the cache hit rate.

The performance of JIT-compiled code is affected by the quality of profiling data, leading to a trade-off between compiled code reuse and possible performance degradation due to differences in profiles across the clients. We focus on the common use case of sharing between instances of the same application where profiles are likely similar (e.g. horizontal autoscaling, FaaS, data-parallel computation). In other cases, we expect the effect to be limited since particularly hot method compilations most affected by conflicting profiles are not cached and rely on individual clients' profiles. We plan to investigate the effect of profiling data variability on the performance of reused native code in our future work.

3.5 Method Serialization Mechanism

The main building block of dynamic AOT relocations is identifying equivalent classes and methods across JVMs. Examples include *inlining guards* (checking an object's class before executing the inlined body) and calls to other compiled methods. Such instruction sequences contain addresses of `RAMClasses`

and methods that need to be patched in a different JVM.

We add another level of indirection to relocatable code by effectively serializing relocation and validation records. For each runtime entity they refer to, the server stores a corresponding *serialization record* with enough information for a client JVM to find the entity and verify that it is equivalent to the one used in the original compilation. Each serialization record also contains the offset from the start of the AOT method body to the location of the corresponding SCC offset field stored in the validation or relocation record.

When the server performs a dynamic AOT compilation in response to a client request, it serializes the compiled method and stores it in its in-memory cache. Serialized methods are self-contained and can be persisted to disk and shared across multiple `JITServer` instances. In our future work, this will enable efficient autoscaling of `JITServer` resources by launching new instances with a warm cache persisted from an existing instance. When a different client JVM receives a serialized AOT method, it iterates through the serialization records, looking up the corresponding entities and updating the SCC offsets to them with their local versions. After successful deserialization, the client proceeds to store the resulting method body in its local SCC (so that execution environments that do not get torn down can take advantage of it in the next run), and loads the method as regular dynamic AOT code.

If any lookups or validity checks fail, deserialization is aborted and the client JVM requests a regular non-cached compilation from the server. Deserialization failures occur infrequently during normal operation: the failure rate for the applications we used in our evaluation is 1-5% during the start phase and less than 1% during warm-up. Such failures happen because the set of classes loaded by the time a method is compiled varies from run to run, therefore a small number of lookups fail as the classes have not yet been loaded.

Relocation and validation records can refer to the following SCC entities: *ROMClass* - immutable part of class metadata; *ROMMethod* - immutable part of method metadata including its bytecodes (part of `ROMClass`); *class chain* - a list of `ROMClass` SCC offsets for classes and interfaces a given class extends and implements.

Identifying Classes and Methods We identify a class across JVMs using a combination of its fully-qualified name and a secure hash (e.g. SHA-256) of the `ROMClass`. We use the hash to efficiently check that a client JVM's version of the class is the same as the one used during compilation. Since the `ROMClass` contains the full description of the class including the bytecodes of all methods, a matching hash guarantees correctness. We identify methods by their defining class, name, and signature (types of parameters and return value).

We use class chains to verify that the whole inheritance chain of a given class is the same across two JVMs. For example, if one of the superclasses or interfaces of a given class is redefined at runtime in the JVM that loads the method, the class chain will not match, even though the class itself has

not changed. The serialization record for a class chain is a list of class serialization records for each class in the chain.

Identifying Class Loaders Since Java classes can be loaded by application-defined class loaders, a class lookup in a running JVM requires a class loader (in addition to class name). We use the following heuristic for class loader identification: we associate each class with the identity of the first class loaded by its class loader. While a regular AOT method refers to a class loader by the class chain of the 1st class that it loaded, a serialized AOT method refers to it by the *name* of the first class that it loaded. We maintain the 3-way mapping between a class loader and the name and the class chain of the first class that it loaded, in each client JVM. We update this mapping at runtime when the JVM loads or unloads classes and creates or destroys class loaders.

The identification heuristic can fail in edge cases described below, however, that does not affect the correctness of compiled code. While we observed no class loader identification failures in our evaluation, they are still possible in rare cases.

Assume that in the compilation environment, RAMClass C1 is the first one loaded by L1. Cached methods that refer to L1 identify it by the name of C - the ROMClass that C1 is based on. In the load environment, RAMClass C2' is the first one loaded by L2' - a different class loader, and then later RAMClass C1' is the first one loaded by L1' (the correct class loader matching the compilation environment) from the same ROMClass C. As a result, loading a cached method can result in using a wrong RAMClass (one loaded by the incorrectly guessed L2'). However, RAMClass pointers are only used directly in generated code in *guards* as described above. A mismatching RAMClass pointer can only affect performance (execution will take the slow path of making a virtual call) while correctness is preserved. In other types of relocations, RAMClass addresses are not present in the native code, and are only used to verify class chains and locate RAMMethods, which are shared by both RAMClasses. Another possibility is that L1' might load a different class first, and in this case cached methods that refer to it simply will not be loaded.

JVM Environment Compatibility Each AOT method is implicitly associated with an *AOT header* - a data structure that describes the compilation environment: CPU features, JVM configuration, etc. Local SCC stores a single instance of this structure. All JVM instances that store or load AOT code in the SCC must have a matching configuration. Serialized AOT methods store the AOT header of the JVM that it was originally compiled for. To serve a client compilation request from the cache, the server looks up a serialized method with a compatible AOT header.

Storage and Transfer Optimizations In order to make the serialized AOT method representation more compact for optimal storage and transfer, we store serialization records at the server separately from method bodies, and serialized AOT methods refer to them by unique IDs. When responding to

a client compilation request with a cached serialized AOT method, the server sends the serialized method body along with all the serialization records it refers to that the client has not yet received. In order to reduce network traffic and deserialization overhead, the client caches serialization records received from the server, and the server keeps track of the record IDs that are already cached at the client.

The size of a populated JITServer cache of compiled methods is ~30-130 MB in our experiments depending on the application, which is smaller than the pre-populated local SCC (~65-170MB) since the JITServer cache only stores ROMClass hashes instead of full class metadata. Since the set of compiled method varies across multiple clients (even running the same application), the JITServer cache accumulates a larger number of methods compared to the local SCC which is only populated once. The cache size can be reduced by pruning the "tail" of less popular methods, e.g. ones that do not get reused within a certain time period. In our experiments, 7-12% of cached methods were never reused.

End-to-End Example We provide a simple example that illustrates how a compiled method body is serialized by the JITServer and later deserialized and loaded by a client JVM. Consider the following Java code:

```
abstract class A {
    abstract void m1();
}
class B extends A {
    void m1() { ... }
}
class C {
    static void m2(A o) {
        o.m1(); // inlined
    } // as B.m1()
}
```

Assume that the JIT has inlined the call to `o.m1()` in `C.m2()` as a devirtualized call to `B.m1()` as profiling showed that the runtime class of `o` is normally `B`. The inlined body of `B.m1()` (see pseudo-assembly below) is preceded by a *guard* that checks that the RAMClass of `o` is indeed `B`, otherwise it jumps to the slow path that makes a virtual call.

```
cmp rax, ramclass_B; rax contains RAMClass of o
jne slow_path      ; ramclass_B is hard-coded
...                ; inlined body of B.m1()
slow_path: ...     ; virtual call to o.m1()
```

Figure 2 illustrates the entities described below. The metadata of the dynamically AOT-compiled method `C.m2()` contains a relocation record for class `B` that will be used to patch the RAMClass address in the comparison instruction in the guard when the method is loaded in another JVM. This record stores the SCC offset of the class chain for `B`, and the SCC offset of the class chain identifying its class loader `L`. This identifying class chain is the one for the first class that was loaded by `L`. Assume that this class was `Object`, i.e. `L` is the bootstrap class loader. The class chain for `B` is a list of SCC offsets of ROMClasses `B`, `A`, `Object`. The class chain identifying `L` is a single SCC offset of ROMClass `Object`. The SCC offsets are only valid for the client JVM that originally requested this compilation.

To serialize `C.m()`, the server creates the following records corresponding to the relocation record for class `B`:

Figure 2: Serialization records for method `C.m2()`

- Class loader serialization record identifying L by the name of the first class it loaded - "Object".
- Class chain serialization record for B .
- Class serialization records for B , A , $Object$. Each record contains the hash of the ROMClass and its name.

When a different client JVM receives this serialized method, it performs deserialization as follows:

1. Find the class loader L' as the one that had a class with the name "Object" as the first class that it loaded. In this case it will be the bootstrap class loader.
2. Lookup RAMClass B' by name "B" in the class loader L' .
3. For each class in the class chain (i.e. B' , A' , $Object$), compute the hash of the ROMClass and compare it with the hash stored in the corresponding serialization record.
4. Update the values of the SCC offset fields in the validation record. The class chain offset will now point to the class chain for B' stored in the local SCC, and the loader identifying offset will point to the class chain for $Object$.

Assuming no failures, the method is now deserialized - all its validation and relocation records point to valid SCC entities - and can be stored in the local SCC for future reuse. The client then relocates the method body by patching the RAMClass address in the comparison instruction in the inlining guard so that it points to the RAMClass B' , and installs it in the JVM code cache. The compiled native code of `C.m2()` can now be executed correctly in this JVM.

4 Evaluation

Our evaluation answers the following research questions:

- Is remote JIT compilation efficient without caching?
- How does remote JIT compilation affect start-up and warm-up times and memory footprint of application instances with different CPU and memory constraints?
- What is the effect of caching on the *overall cluster-wide* resource usage and application density?
- Can remote JIT improve performance if the client JVM already has a pre-populated local SCC (see Section 2.2)?
- What is the effect of remote JIT and caching on the latencies of compilation requests, compared to local JIT?

| Name | Framework | Database | Methods compiled | |
|-----------|--------------|----------------|------------------|---------|
| | | | Start | Total |
| AcmeAir | Open Liberty | MongoDB | ~3,000 | ~11,000 |
| DayTrader | | DB2 | ~5,000 | ~25,000 |
| PetClinic | Spring | H2 (in-memory) | ~5,000 | ~6,000 |

Table 1: Application benchmarks

| Type | CPU | Memory | Storage |
|------|----------------------------|--------|---------------|
| A | 16-core AMD EPYC 7302P | 256 GB | 2× NVMe RAID0 |
| B | 14-core Intel Xeon E5-2680 | 128 GB | SSD |

Table 2: Hardware configuration

- How does caching affect the scalability of JITServer (i.e. how many clients can it effectively serve at the same time)?
- Does caching allow JITServer to handle higher latency?

Applications We used the following 3 applications in our experiments: AcmeAir [1] - an airline booking system, DayTrader [8] - a stock trading platform, and PetClinic [15] - an animal hospital information system (the de-facto main benchmark for the popular Spring framework). All 3 are web applications; information about them is summarized in Table 1. We used Apache JMeter to generate the workload for all the applications. These applications are multi-tier, end-to-end benchmarks that are more representative of cloud workloads than benchmarks like SPECjvm2008 [14], SPECjbb2015 [12], and SPECjEnterprise2018 [13] typically used for JVM performance evaluation. Individual benchmarks in the SPECjvm suite are essentially microbenchmarks from the JIT perspective with a small number of JIT-compiled methods. SPECjbb and SPECjEnterprise are heavy, long-running (over 2 hours) workloads unsuitable for analyzing cold start performance. Moreover, DayTrader is a comprehensive JavaEE benchmark that uses most of the same technologies as SPECjEnterprise.

Experimental Setup We ran the experiments on a cluster of 11 machines as described in Table 2: 8 machines of type A and 3 slightly less powerful machines of type B. All machines run Ubuntu 18.04 and are connected with a 10 GBit/s Ethernet network (used in all experiments unless specified otherwise) and a 100 GBit/s Infiniband network.

Type A machines run the instances of the application, the database, and the JITServer, while type B machines run JMeter instances (one per application instance) that generate the load. We use a single JITServer instance running on a dedicated machine in all experiments. While co-locating JITServer instances with application JVMs is a viable deployment option, we evaluate JITServer in the fully remote setting to show "worst case" performance. Application instances run in Docker containers with 1 CPU and 1 GB of memory, unless specified otherwise. This container size is roughly equivalent to an AWS EC2 t2.micro instance which is commonly used for modern cloud workloads [3]. The number of JMeter threads is chosen to saturate the throughput of the application instance. The number of database instances is chosen for each benchmark such that the DB is not a bottleneck. The JVMs are configured to use the default heap size and GC policy. Each

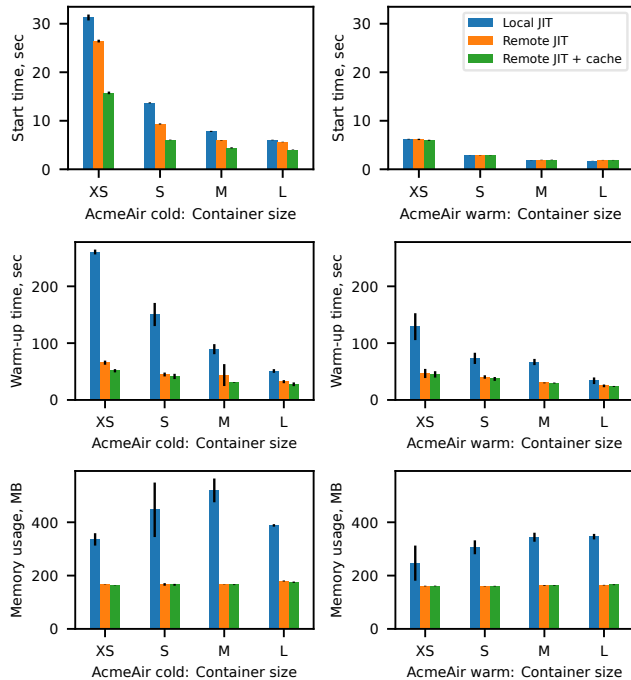

Figure 3: AcmeAir performance: (a) cold; (b) warm

data point is averaged over 5 runs, unless specified otherwise; the error bars on the graphs represent standard deviation.

We compare application performance in three JIT compilation modes: *local*; *remote* without caching, and *remote with caching*. Depending on the experiment, we deploy application instances without a pre-populated local SCC (*cold runs* - default unless specified otherwise), or with an SCC populated by only starting an application instance (*warm-start runs*), or by also applying load to it (*warm runs*). While JITServer supports sharing the cache of compiled code across applications, in this paper we focus on the very common use case of multiple instances of the same application. We do not compare with static AOT compilation in HotSpot and GraalVM. Such direct comparison would not be fair since OpenJ9 is a different JVM, and static AOT only supports a subset of Java. We are unable to compare against the remote JIT compiler in [26] since its implementation has not been made available.

4.1 Application Performance and Footprint

We measure how remote JIT compilation (with and without caching) affects the start-up and warm-up performance and memory footprint of a JVM instance. We run the applications in Docker containers of the following sizes: *XS* (0.5 CPU, 512 MB of memory); *S* (1 CPU, 1 GB); *M* (2 CPUs, 2 GB); and *L* (4 CPUs, 4 GB). When JITServer cache is enabled, it is populated by a single run of the application. We define the performance metrics as follows:

- *Memory usage* - peak resident set size (RSS) of the JVM.
- *Start time* - time since the start of the JVM process until the application is ready to handle client requests.

Figure 4: DayTrader performance: (a) cold; (b) warm

- *Warm-up time* - time from the moment the load is applied until the application reaches 90% of its peak throughput.

Figures 3(a), 4(a), and 5(a) show results for *cold* runs of AcmeAir, DayTrader, and PetClinic respectively. Remote JIT without caching reduces memory footprint by up to 68%, start time by up to 40%, and warm-up time by up to 80% compared to local JIT. The addition of caching reduces start and warm-up times even further (especially for smaller container sizes since they have less CPU available for local JIT): by up to 58% and 87% for start and warm-up respectively. There is still a non-negligible number of compilations (including heavy recompilations at high optimization levels) during warm-up that are not served from the JITServer cache: 24-32% depending on the application, compared to only 7-15% during the start phase. As a result, the effect of caching on warm-up time is relatively smaller compared to start time.

Figures 3(b), 4(b), and 5(b) present results for *warm* runs where the local SCC is pre-populated by a previous full run of the application. JITServer still significantly reduces warm-up time (up to 79%) and peak memory footprint (up to 61%), but has no effect on start time since almost all methods compiled during start-up are stored in the SCC and thus do not need to be compiled in a warm run.

Remote JIT with caching is more effective than only using a pre-populated SCC for reducing memory usage and warm-up time. Moreover, these improvements come "for free" as JITServer caching is transparent for the application developer, unlike using the SCC (see section 2.2). Besides, these results represent the advanced and most optimal way to use the SCC which requires very significant developer effort and is rarely

Figure 5: PetClinic performance: (a) cold; (b) warm

done in practice. Caching (local or remote) does not eliminate the need for a JIT compiler. Remote JIT compilation is still a win even with a pre-populated SCC as not all compilations can be cached, and JITServer can make better use of resources, reducing CPU contention and memory footprint.

Application instances reach equivalent peak throughput with local and remote JIT in all the experiments, which is expected since JITServer uses the same set of optimizations and heuristics as the local JIT compiler. The reduction in start and warm-up times is due to the higher degree of parallelism of JIT compilations since the server runs on an additional machine. Arguably, these results do not represent a fair comparison to local JIT as the extra CPU and memory resources used by the JITServer could be used to run other application JVMs instead. In the next subsection we consider *overall system-wide* resource usage, including the JITServer itself.

4.2 Overall System Efficiency

We evaluate the effect of remote JIT compilation (with and without caching) on the *system-wide* resource usage by emulating a cloud deployment where many application instances are brought up and down over a 1 hour period. 64 application slots (one per CPU) are spread evenly across 4 machines. Each slot is used to run a sequence of application instances that execute for a fixed duration (2, 5, or 10 minutes) and stop to be replaced by the next instance. The starting moments of the sequences are staggered with a 10 second interval. We run a single JITServer instance on a separate machine in remote JIT experiments. Each experiment is repeated 3 times.

Figure 6 shows total CPU cost and memory usage (*lower*

is better) in *cold* runs. We define *CPU cost* (measured in milliseconds per request) as the amount of total CPU time used by all JVM instances and the JITServer, divided by the number of JMeter requests served (i.e. useful work done) by all application instances. We use *total CPU time* instead of e.g. aggregate throughput to account for the fact that the JITServer runs on an additional machine that could be used to run more application instances. *Total memory usage* includes the peak RSS of the the JITServer and all concurrent JVM instances.

Remote compilation without caching results in up to 21% *increase* in CPU cost compared to local JIT. On the other hand, caching compiled code at the server effectively amortizes the CPU cost over many clients and results in up to 77% reduction compared to local JIT. The effect is larger for shorter application lifespans since the start-up and warm-up phases with high JIT activity take a bigger portion of the run time. We expect application run times in the cloud to be on the lower end. The CPU cost improvements for PetClinic are relatively smaller since it has fewer methods compiled during warm-up (see Table 1). Remote JIT with caching also significantly reduced start times in these experiments - by 32-58%.

Remote JIT delivers benefits in terms of memory footprint: it reduces total memory usage by up to 62% compared to local JIT compilation. Peak total memory footprint is smaller with JITServer because memory usage spikes caused by heavy compilations from multiple clients are unlikely to align at the server. The 2-minute DayTrader runs are the exception; the extra memory footprint is due to faster heap expansion caused by higher allocation rates since the application reaches higher throughput compared to other JIT compilation modes.

The results for *warm-start* runs (with a pre-populated SCC) are shown in Figure 7. Remote JIT without caching can still have higher CPU cost (e.g. by 9% for 2-minute PetClinic runs) than local JIT with SCC, while JITServer with caching matches or surpasses the performance of local JIT with SCC. Remote JIT still achieves lower (by up to 45%) total memory usage. JITServer not only achieves better resource utilization than using a pre-populated local SCC, but does it transparently without the additional developer effort associated with managing the SCC (see Section 2.2). The two approaches can be combined, in which case adding JITServer reduces CPU cost by up to 53% compared to local JIT.

The main implication of these results for cloud computing is that remote JIT with caching allows to increase application density, even after accounting for the resources used by the JITServer. We can fit more application instances into the same amount of hardware resources since each instance requires less memory and uses the CPU cycles to do more useful computation. With caching, JITServer does not simply move the overhead around - it uses the resources more efficiently.

4.3 Compilation Request Latencies

We measure two compilation latency metrics: (i) *compilation time* taken to serve the request either locally or remotely, and

Figure 6: Overall efficiency in cold runs (*lower is better*)

(ii) *total queuing time* - from the moment the compilation is first scheduled by the JVM (e.g. the method reached its invocation threshold) until its completion. Figure 8 shows the resulting CDF (using a logarithmic scale on the X axis) for the AcmeAir benchmark when the JITServer is given all the resources of its host. Figure 9 represents the configuration with *equal CPU resources*: 2 CPUs for local JIT, and 1 CPU each for the JITServer and the client JVM. The results for other benchmarks are very similar and thus omitted.

The results show that individual remote compilations take longer than the local ones, unless the JITServer has more CPU resources. In the latter case, longer (more CPU-intensive) compilations take less time at the JITServer thanks to ample CPU resources, while cheaper compilations take longer than locally - their latency is dominated by communication. Total queuing times are still shorter than with local JIT even with limited JITServer CPU due to increased parallelism: the CPU work is overlaid with waiting for the network. Caching compiled code at the JITServer dramatically reduces compilation request latencies, thanks to the 68-76% cache hit rate.

4.4 Scalability

In order to determine how caching affects JITServer performance with an increasing number of clients, we run a variable number - between 1 and 64 (80 for PetClinic) - of application instances that use the same JITServer instance. Application JVMs start simultaneously and without a pre-populated local SCC, in order to maximize the load on the server. We measure the *full warm-up time* (sum of start and warm-up times) averaged over all concurrent JVM instances. Remote JIT is

Figure 7: Overall efficiency in warm-start runs (*lower is better*)

more efficient than local for a given number of clients only if the full warm-up time is lower. When the server becomes overloaded, the clients accumulate a backlog of compilation requests, which results in slower warm-up.

Figure 10 shows the full warm-up times for each number of instances (normalized to the local JIT configuration). We see that JITServer caching dramatically improves scalability: given the same amount of resources available to the server instance, it can sustain load from a larger number of clients, while improving their start-up and warm-up performance. The cost of JIT compilation is reduced and effectively amortized over a large number of concurrent clients by avoiding the majority of repeated compilations with caching.

These results represent JITServer performance in a worst case scenario. In a real deployment, we expect client JVM starts to be staggered, providing more opportunities for statistical multiplexing, which in turn should allow JITServer to handle an even larger number of clients without saturating. Additional JITServer instances can be brought up on demand, allowing linear horizontal scaling since JITServer only maintains soft state - the cache of compiled methods.

4.5 Effect of Network Latency

To determine how caching affects JITServer performance with increasing network latency, we run a single application instance with varying values of round-trip network latency between the client JVM and the JITServer. We measure the *full warm-up time* (start + warm-up) and compare it with using local JIT compilation: remote compilation improves performance if it results in faster warm-up. As latency grows,

Figure 8: Compilation latencies: unlimited JITServer resources

Figure 9: Compilation latencies: equal JIT CPU resources

each compilation request takes more time, and the server eventually becomes unable to compile methods faster than the local JIT compiler. We used the 100 Gbit/s Infiniband network for the smallest latency value - 15 microseconds. The 10 Gbit/s Ethernet network has a latency of 45 microseconds. We emulate the additional latency for subsequent data points using the `netem` module in the Linux kernel.

Figure 11 shows the results for latencies up to over 8 milliseconds. We can see that caching allows JITServer to tolerate higher network latencies (~4-8 ms, compared to ~2-4 ms without caching) since cache hits only incur a single round-trip. Caching compiled code reduces the average number of messages per compiled method by ~54% (from ~42-47 to ~19-22 depending on the application), and the total amount of data transferred per client by ~30% (from ~190-800 MB to ~140-580 MB depending on the application). On the other end of the spectrum, bringing the latency down to microseconds only slightly improves performance. JITServer performs very well for latencies in the hundreds of microseconds which are typical in cloud datacenters. Performance in high-latency scenarios can be further improved by increasing the maximum number of client compilation threads (see Section 3.1). In our future work, we plan to investigate using remote JIT compilation in high-latency environments such as edge computing.

Summary of Results Our evaluation shows that:

- Remote JIT cannot be fully efficient without caching - it often increases total system-wide CPU cost (by up to 21%).
- Caching compiled code allows JITServer to reduce cluster-wide resource usage (by up to 77% for CPU and up to 62% for memory) and increase application density.
- JITServer significantly reduces application start-up and warm-up times (by up to 58% and 87% respectively) and memory footprint, especially in smaller containers.
- Caching dramatically improves JITServer scalability and allows it to effectively handle more concurrent clients and tolerate significantly higher network latency (up to 8 ms).

5 Conclusion and Future Work

In this paper we explored JIT compiler disaggregation as a means to improve the performance and memory utilization of JVMs running in the cloud. We described JITServer, our disaggregated JIT compiler implementation in a production grade JVM, which supports the caching and reuse of compiled code across JVMs running on different hosts, and effectively amortizes JIT compilation costs over many client JVMs.

The experimental results showed excellent improvements in start-up time, warm-up time and memory footprint: JITServer is able to speed-up JVM start-up by as much as 58% and to reduce warm-up times by up to 87%, without a degradation in peak throughput. Moreover, the overall system-wide peak memory footprint is reduced by up to 62%, which should make it possible to reduce operational costs by increasing application density. Caching and reusing compiled code allows JITServer to reduce overall CPU cost by up to 77%, showing that JITServer enables cloud users to do more useful computation with less resources.

Our future work will explore prefetching of server-cached code and predicting hot methods to hide compilation latency and further reduce cold start times. We will study the trade-off between the performance of relocatable code and the JITServer cache hit rate. We will investigate ways to improve the JIT compiler in the disaggregated setting, e.g. utilizing profiling data from many clients, efficiently sharing compiled code across applications, and automatically sizing and scaling compilation resources. We plan to apply JITServer to other workloads such as FaaS, microservices, and data analytics.

A Artifact Appendix

Abstract

We provide the open source implementation of JITServer (as part of the OpenJ9 project), as well as the automated benchmarking platform that we used in our experimental evaluation. Our results have been successfully reproduced in artifact evaluation.

Scope

Our artifact can be used to run all the experiments described in Section 4 in order to validate the main claims in our paper, most importantly:

- JITServer can reduce application start time and warm-up time and system-wide CPU and memory usage for JVM-based applications running in containers with limited resources (which are common in the cloud).
- Caching dynamically compiled code at the JITServer is necessary to fully achieve the reduction in overall CPU usage and application start time.

Note that the experimental results are expected to be slightly different from the ones reported in this paper (even on the same hardware) since the OpenJ9 implementation has evolved since we conducted those experiments. However, the main conclusions should still hold.

Contents

The artifact consists of two parts:

1. The open source implementation of our system, which has been contributed to the OpenJ9 project. JITServer is implemented in ~25 KLOC of C++. The code is integrated into the rest of the OpenJ9 code base.
2. A set of scripts (Python, shell scripts, and Docker files) that automate the benchmark runs used in our evaluation and generate the resulting graphs. We also provide the logs generated by running the full set of experiments reported in this paper.

Hosting

All the parts of our artifact are open source and are hosted on GitHub. The OpenJ9 code base (including JITServer) is split across three separate repositories:

- Eclipse OpenJ9: <https://github.com/eclipse-openj9/openj9>;
- Eclipse OMR: <https://github.com/eclipse/omr>;
- OpenJDK extensions for OpenJ9 (we used JDK 8 in our experiments; newer JDK versions are also available): <https://github.com/ibmruntimes/openj9-openjdk-jdk8>.

The source code of our automated benchmarking platform is available at <https://github.com/AlexeyKhrabrov/jitserver-benchmarks>

Stable forks or branches of these repositories based on the 0.32.0 OpenJ9 release (with minor changes required by our

benchmarking platform, e.g. collecting additional statistics) that were used for artifact evaluation are available as follows:

- OpenJ9: <https://github.com/AlexeyKhrabrov/openj9/tree/atc22ae> (commit 724db2932e5f0abb);
- OMR: <https://github.com/AlexeyKhrabrov/omr/tree/atc22ae> (commit ab24b66665961405);
- JDK: <https://github.com/AlexeyKhrabrov/openj9-openjdk-jdk8/tree/atc22ae> (commit 0b8b8af39a5f1f2f);
- Benchmarks: <https://github.com/AlexeyKhrabrov/jitserver-benchmarks/tree/atc22ae> (commit 8360d90b89744ad1)

Requirements

While JITServer supports a wide range of Linux platforms, our benchmarking setup assumes Ubuntu 18.04 as the OS. It should be possible (although not necessarily easy) to tweak it to work on other Linux distributions. Newer Ubuntu versions might require downgrading to an older GCC version (OpenJ9 currently officially supports GCC 7, but should also support GCC 10). Different Linux distributions will need more tweaks, namely different ways of installing prerequisite packages.

Running the largest experiments reported in this paper requires a cluster of 11 machines with 16 CPU cores each, connected with a 10 Gbit/s network (or at least 1 Gbit/s) with round-trip latency between machines in the low hundreds of microseconds or less. Alternatively, the experiments can be run in a public cloud such as AWS on a cluster of virtual instances with roughly equivalent resources. The benchmark setup requires `sudo` permissions on all the machines. The required amount of storage space is approximately 30 GB on each node (not including the OS).

The hardware and software environment that we used in the experimental setup in our evaluation is described briefly in Section 4 and in more detail in the README document: <https://github.com/AlexeyKhrabrov/jitserver-benchmarks/tree/atc22ae#environment-used-in-our-evaluation>.

Usage

Detailed instructions describing how to set up and run the benchmarks and generate the results can be found in the README of the artifact repository: <https://github.com/AlexeyKhrabrov/jitserver-benchmarks>

Acknowledgements

We thank the anonymous reviewers and the shepherd for their feedback that helped us improve the paper, as well as the anonymous AEC members for their help in identifying and resolving issues in our artifact submission. We are grateful to the OpenJ9 developer community for their help in contributing

our code to the OpenJ9 project. This research was supported in part by IBM CAS Canada and an NSERC CRD grant.

RIKER: Always-Correct and Fast Incremental Builds from Simple Specifications

Charlie Curtsinger
Grinnell College

Daniel W. Barowy
Williams College

Abstract

Build systems are responsible for building software correctly and quickly. Unfortunately, traditional build tools like `make` are correct and fast only when developers precisely enumerate dependencies for every incremental build step. Forward build systems improve correctness over traditional build tools by discovering dependencies automatically, but existing forward build tools have two fundamental flaws. First, they are incorrect; existing forward build tools miss dependencies because their models of system state are incomplete. Second, they rely on users to manually specify incremental build steps, increasing the programmer burden for fast builds.

This paper introduces RIKER, a forward build system that guarantees fast, correct builds. RIKER builds are easy to specify; in many cases a single command such as `gcc *.c` suffices. From these simple specifications, RIKER automatically discovers fast incremental rebuild opportunities. RIKER models the entire POSIX filesystem—not just files, but directories, pipes, and so on. This model guarantees that every dependency is checked on every build so every output is correct.

We use RIKER to build 14 open source packages including LLVM and memcached. RIKER incurs a median overhead of 8.8% on the initial full build. On average, RIKER’s incremental builds realize 94% of `make`’s incremental speedup with *no manual effort* and *no risk of errors*.

1 Introduction

Build systems specify how code and other assets should be transformed into executable software. They capture compilation procedures left unstated in the source code itself. Build systems make the process of building software more reliable, since they free programmers from having to reproduce long sequences of build commands after making a change.

To be useful, build systems should satisfy two goals. First, builds must be correct: running a build should always have the same effect, whether code was built previously or not. Second, builds must be fast: they should perform the minimum amount of work required to update a build in response to a

change. These goals are often in tension. Builds that are simple to specify expose few opportunities for fast incremental updates, while complex incremental builds are more likely to be incorrect. To illustrate this challenge, we begin with an example build specification for `make`, one of the earliest and most widely-used build tools [8].

```
program ①: main.c x.c x.h y.c y.h ②  
gcc -o program main.c x.c y.c ③
```

A `make` build specification, written in a `Makefile`, lists a collection of *build rules*. The example above shows a rule that produces a single program from three source files and two include files. Each target is composed of three parts: ① a *target name*, usually the name of an output file; ② a list of *dependencies*, which `make` calls “prerequisites,” required to produce the target; and ③ a *recipe* that includes the build commands needed to produce the target from the dependencies.

At the start of each build, `make` compares the last modification time of every target with its dependencies. When a dependency is newer than the target, `make` runs the recipe to update the target. When a dependency does not exist, `make` recursively runs the rule that builds the dependency.

The key insight in `make`’s design is that developers rarely change an entire codebase between builds. Rebuilds can run faster by doing work proportional to the number of changed dependencies, not the total number of files. In the simplest case, when no dependencies change, `make` does nothing at all.

It is easy to see that the example `Makefile` is correct because all the dependencies are present and only a single build command is needed. Unfortunately, this build is also inefficient. Changing `x.c` will cause `gcc` to recompile all three `.c` files, even though `y.c` and `main.c` are unchanged. The cause of this inefficiency is that the build is monolithic: there is only one target that depends on all source files, so `make` must run a full build when any source file changes.

Monolithic builds are prohibitively expensive for larger projects. For example, a full build of LLVM takes nearly 20 minutes when run in parallel on a typical developer workstation—far too long for a developer to wait to test a

small code change. Not surprisingly, large projects often have incremental build specifications. To produce an incremental `make` build, developers must break a specification into smaller rules, exposing intermediate targets. The following modifies the original `Makefile` so that it can be built incrementally.

```
program: main.o x.o y.o
    gcc -o program main.o x.o y.o
main.o: main.c x.h y.h
    gcc -c -o main.o main.c
x.o: x.c
    gcc -c -o x.o x.c
y.o: y.c y.h
    gcc -c -o y.o y.c
```

The updated specification states how to build a `.o` file from each source file, and how those `.o` files are combined into the final target, `program`. The new `Makefile` describes the same work that `gcc` performs internally; internal steps have simply been exposed so that `make` can run them or skip them during an incremental rebuild. With this `Makefile`, modifying `x.c` no longer rebuilds every output. Instead, the build generates a new `x.o`, linking it with the other `.o` files already on disk.

This `Makefile` also illustrates the dangers inherent in more complex build specifications: missing dependencies. Suppose `x.c` includes `x.h`. The original `Makefile` is correct, but the refactored one is not because changing `x.h` does not trigger a rebuild of `x.o` as it should. The implication of such a bug is that a developer with a previously-built working copy could end up with different output than another developer who starts with a clean copy of exactly the same source code.

An incremental build must be *consistent* with the full build; it should always produce output that could have come from a full build. `Make` and build tools like it do not guarantee this property because they do not check for missing dependencies. These errors occur with alarming frequency. A recent study showed that more than two-thirds of the open-source programs analyzed had serious build specification errors [28].

To address build errors, recent work proposes the idea of a *forward build system* [29]. Build systems like `make` are “backward” because evaluation proceeds from the final output rules, recursively building dependencies as needed. A forward build specification instead lists a sequence of commands, in order, that perform a full build. Critically, forward build systems discover dependencies automatically using program tracing instead of asking users to enumerate dependencies. On rebuild, a forward build system runs only the commands necessary to update the build, just as `make` does. When correctly designed and implemented, forward build systems guarantee correctness because they never miss dependencies.

Unfortunately, prior forward build systems miss dependencies because they fail to account for the complexity of real builds. Worse, they require users to manually specify incremental build steps. As a result, prior forward build systems are neither automatically correct nor automatically fast.

This paper introduces RIKER, a forward build system that

delivers the benefits of an incremental build system with the simplicity of monolithic specifications. RIKER substantially advances the state of the art in forward build systems by using a completely different algorithmic approach. With RIKER, efficient incremental builds can be specified using a single build command like `gcc *.c`.

RIKER captures dependencies on directories, pipes, links, and sockets—not just files—ensuring that builds are correct. RIKER infers fine-grained steps from monolithic build specifications, ensuring that builds are fast. In the above example, RIKER captures the execution of the C compiler (`cc1`), assembler (`as`), and linker (`ld`), can run these commands incrementally, and in many cases in parallel, to update the build. In short, RIKER makes it possible for users to specify builds that are simple, correct, and efficient.

Contributions

Tracing and TraceIR. We present a high-performance system call tracing mechanism that generates dependence-checking programs in the novel TraceIR language (§4). TraceIR captures all of a build’s state interactions—including, but not limited to, paths, files, directories, and pipes. TraceIR facilitates correct handling of circular and temporal dependencies, complexities that occur in real builds.

RIKER Build Algorithm. The RIKER algorithm performs efficient incremental builds by mixing emulation of previously-recorded TraceIR with re-execution of commands whose dependencies have changed (§5).

Implementation and Evaluation. We present an implementation of RIKER for Linux, and evaluate this implementation by using it to build 14 real-world software projects (§6). Our evaluation shows that RIKER is a significant advance over the previous state of the art in forward build tools, automatically performing incremental builds that are competitive with manually-written `make` builds. RIKER is available under an open-source license at <https://rkr.sh>.

2 Related Work

Build systems have evolved significantly since `make`’s introduction in 1976 [8, 21]. However, all build systems share the two goals we identify in the introduction: builds must be correct and they must be fast. Build systems differ substantially in their configuration, the precision of their dependency tracking, how changes are detected, and the level of manual effort required to use them. These differences, which we discuss below, are summarized in Table 1.

Backward Build Systems. The `make` build system and most of its successors are *backward build systems*. With a backward build system, the user writes a rule for each target produced by the build, lists the dependencies required to produce the target, and provides the commands required to create the target from its dependencies. When a target’s dependency does

| | RIKER | ✓ | ✓ | ✓ | ✓ | ✓ | ✓ | ✓ |

Table 1: A comparison between RIKER and prior build tools. A build system is *language agnostic* if it can build projects written in any source language or combination of languages, and has *no DSL* if builds can be specified in a general-purpose language that is executable independent of the build system. A build system is *precise* if it ensures that a specification captures all dependencies. It is *general* if it allows cyclic dependencies, anti-dependencies, and dependencies on non-file objects. A build system is *automatic* if it discovers dependencies or incremental builds without manual specification. A tool that supports *dynamic* incremental builds can discover dependencies while a build runs. A ✓* indicates partial support, and ✓^λ indicates that a feature’s support is language-specific.

not exist, a backward build system calls the rule that produces the dependency. Such build specifications are essentially an edge-by-edge encoding of a dependence graph.

Make, Tup [27], Shake [22], and Ninja [1] are all examples of backward build systems that require a dependence graph encoding. Writing build specifications for these tools can be burdensome. CMake [4], Ant/Maven [2, 3], SCons [26], and Pluto [5] reduce this burden by providing standard templates. Templates encode common build procedures like producing an executable from a collection of C source files. These tools automatically discover dependencies and run incremental builds, but only for supported languages. Users must provide extensions to these build tools before they can use them to build projects that use unsupported languages.

The early and innovative Vesta build system specifies builds in a general-purpose modeling language [12, 13]. Although users encode dependencies manually, Vesta uses a form of black-box tracing at the filesystem layer to identify and cache unspecified build outputs for incremental speedups. As Vesta is also a source control management tool, it can correctly reuse cached build objects in a distributed setting. Vesta can only skip work for explicitly enumerated build steps.

Buck [7] and Bazel [11] focus on ensuring that dependencies are *precise* by intentionally failing when any dependency is not explicitly provided. This is in direct contrast to Make, Tup, and Shake, where missing dependencies can lead to incorrect builds. Like CMake, Buck and Bazel simplify the process of specifying incremental builds with templates for supported languages. Buck, Bazel, and Pluto also offer some degree of dynamism when building; they can discover some additional dependencies or prune work as the build proceeds.

RIKER differs from all these tools because it precisely captures fine-grained dependencies and provides automatic speedups without manual specification, and it does so for projects written in any programming language.

Forward Build Systems. Memoize [19], Fabricate [14], and Rattle [29] use tracing to discover dependencies from a sequence of build commands that should run in order. These systems guarantee precise dependencies while remaining language agnostic. However, all of them are limited to modeling file state. A change to unsupported state, like a directory, does not trigger a rebuild, producing an incorrect rebuild. As we discuss in this work, correct builds must model not just files, but inode metadata, directories, symbolic links, hard links, pipes, and sockets. Correct build systems must also model the *absence* of such state. Existing forward build tools also have limited ability to produce fast incremental builds. Compiler drivers like `gcc` launch many separate sub-commands to compile, assemble, and link programs. Prior forward build systems require users to enumerate incremental build steps, which makes writing build specifications more difficult.

Like the above tools, RIKER is a forward build system. RIKER substantially improves the state of the art by automatically inferring fine-grained build steps. RIKER can directly invoke sub-commands called by wrapper programs like `gcc`. Sub-command execution is possible because RIKER’s dependence tracking is both precise and complete.

Separation of Concerns. Many build tools tackle additional tasks, such as platform detection or compilation in a distributed setting. For example, Autoconf [9] and Automake [10] detect characteristics of the local system to generate build configurations, usually as a precursor to running `make`. Buck, Bazel, Vesta, and CloudBuild [6] offer support for distributing builds on cloud services. We regard these objectives to be orthogonal to this work. Since a RIKER build specification is just a program, it can include configuration steps. And we suspect that RIKER’s precise dependency tracking may make it easier to distribute builds across machines, although we have not explored this topic.

RIKER’s design is strongly influenced by the UNIX philosophy to make each program “do one thing well” [20]. There-

fore, we focus this work narrowly on one problem: to build software correctly and quickly. This paper provides evidence that the key to building software correctly and quickly is the accurate detection and handling of changed dependencies, regardless of language. The fact that RIKER can be used to orchestrate compilation *for* any language, using a specification written *in* any language, is a useful property that emerges from the exclusive pursuit of this sole concern.

3 Overview

RIKER builds software using a simple specification called a Rikerfile. A Rikerfile is typically a short shell script, although it can be any executable that performs a full build. RIKER is designed to spare developers the error-prone work of specifying dependencies. Instead, RIKER discovers them automatically as a Rikerfile executes. RIKER uses system call tracing to capture all of a build’s stateful interactions, which it records in a novel intermediate representation called TraceIR. A TraceIR *transcript* is a *program* that describes a build’s dependencies, operations, and effects (see §4).

When a user requests a rebuild, RIKER evaluates the stored transcript instead of running a full build (see §5). Evaluation updates an in-memory model of system state; the model captures the effects that *would occur* if a full build were run again. Every statement in the TraceIR language is a predicate: whenever the modeled result of a TraceIR statement differs from the observed outcome of the previous build, a dependency has changed. Any command whose dependencies change must be re-executed to update the build.

During TraceIR evaluation, RIKER must decide: should a command be *executed*, or can it be *skipped*? If a command is executed, RIKER actually runs the command using the `execve` system call, tracing its execution and replacing its old TraceIR statements in the transcript. If a command is skipped, RIKER instead *emulates* the command, replaying its effects (if it has any) in the model and only *syncing* those effects to the filesystem at the end of the build or when an executed command needs to observe them. In general, emulation is orders of magnitude faster than execution. RIKER runs fast incremental builds by skipping commands whenever it can; the number of executed commands is roughly proportional to the number of changes.

RIKER repeatedly re-evaluates the entire trace until no changes are found. Re-evaluation is necessary because an executed command can change a dependency for another command. Instead of conservatively running all commands that *might* observe changes, RIKER defers the decision to execute until it can prove that a command *must* execute. Once no commands must execute, the build is “up to date” and RIKER saves the updated transcript for use in the next rebuild.

3.1 Examples

In this section, we highlight three scenarios from the working example (from §1) that illustrate RIKER’s operation. The

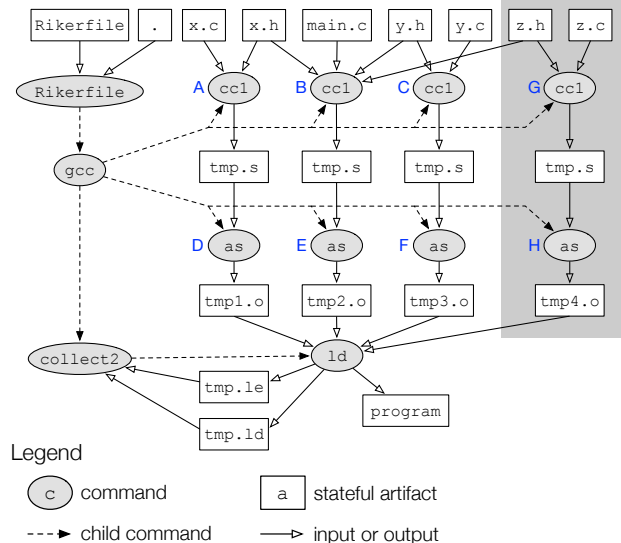

Figure 1: A dependency graph for the running example. Dashed edges show commands launching child commands, and solid edges indicate inputs and outputs. The grey box contains the modification induced by adding `z.h` and `z.c` to the build in **Scenario 2**.

following Rikerfile specifies the example build:

```
#!/bin/sh
gcc -o program *.c
```

Scenario 1: Running the first build. A user runs `rkr` to perform a build. When `rkr` is invoked with no saved state RIKER starts a full build by executing Rikerfile.

Figure 1 is a dependence graph for the running example. Oval vertices represent *commands*, which correspond to programs run via `exec` system calls. Rectangular vertices represent stateful *artifacts* such as files or directories. Dashed edges indicate that a parent command *launched* a child command. Solid edges indicate a command’s input or output.

In contrast to many other build systems, RIKER’s build algorithm does not store build information as a dependence graph. Dependence graphs lack critical temporal information needed to disambiguate rebuild logic that arises from circular dependencies. We show Figure 1 to illustrate that even simple builds have complex dependence structure that RIKER can exploit. In fact, for clarity, Figure 1 omits a great deal: dependencies on system includes, shared libraries, the executable files for each command, and intermediate states of artifacts written multiple times during the build.

When the Rikerfile command launches `gcc`, it launches three instances of `cc1` in turn. Each `cc1` instance compiles a `.c` file (and any included `.h` files) to a `.s` assembly file. `gcc` also launches three instances of `as` to produce `.o` object files from each `.s` input. Finally, `gcc` launches the `collect2` command, which launches the linker `ld`. `ld` redirects `stdout` and `stderr` to temporary files which can cause `collect2` to rerun the linker with different options. Note the cycle between `collect2` and `ld`; this dependence cycle is present in every build that uses `gcc`. Also observe that `gcc` repeatedly reuses

the same `tmp.s` temporary file, truncating it at the start of each `cc1` execution. File reuse and cyclic dependencies occur frequently in builds.

Instead of a dependence graph, RIKER operates over a TraceIR transcript. RIKER translates every intercepted system call into a sequence of TraceIR statements. The following transcript excerpt is generated during our example build:

```
1 sh_0 = Launch(rkr, "sh Rikerfile", [...])
2 r16 = PathRef(sh_0, CWD, ".", r--)
3 ExpectResult(sh_0, r16, SUCCESS)
4 MatchMetadata(sh_0, r16,
  [uid=100, gid=100, type=dir, perms=rwxrwxr-x])
5 MatchContent(sh_0, r16, [dir: {"Rikerfile",
  "main.c", "x.c", "x.h", "y.c", "y.h"}])
```

The transcript above records that RIKER launched the `Rikerfile` program (line 1). Linux resolved the current working directory path (line 2) without error (line 3), and the resolved directory has the given metadata and directory entries. During tracing, RIKER interprets all transcribed information as what *should happen* during the normal course of a build. While `Rikerfile`'s access of the current working directory's path resolved without error in this example, path resolution failing with `ENOENT` is a normal occurrence whose outcome must be recorded. For example, when the user types `gcc` at the prompt, UNIX may first try to access `gcc` in `~/bin`, which will fail if `~/bin` does not contain `gcc`. This behavior is the result of the fact that UNIX searches the user's `$PATH` during resolution [16]. The observed sequence of failures is a build dependency, and any change in failures implies that a build must rerun. We call failing resolutions *anti-dependencies*.

In the next section, we examine how the above transcript guides a rebuild after a user makes a code change. We defer discussion of TraceIR semantics to Section 4.3.

Scenario 2: Adding a file. Suppose a user adds files `z.c` and `z.h` and modifies `main.c` to include `z.h`. The user then runs `rkr` to update the build. The grey box in Figure 1 shows the effect of the change on the build's dependence graph. An efficient build system should not rebuild files unrelated to a change. Here, `tmp1.o` and `tmp3.o` do not need updating since they do not depend—even transitively—on any of the changes. At the very least, `cc1` and `as` should be called to compile `main.c` and `z.c`, and `collect2` and `ld` should be called to link the output to our preexisting object files. In fact, the very least is exactly what RIKER does here.

RIKER performs an incremental rebuild of the example by evaluating the TraceIR from the previous build. We assume the user does not change ownership or permissions for the current directory, so lines 1–4 evaluate just as before. However, line 5, which depends on directory contents, reports a change because the current directory contains the new files `z.c` and `z.h`. RIKER therefore reruns and traces the `Rikerfile`. When the `Rikerfile` command is rerun, the `Rikerfile`'s portion of the transcript is replaced with newly generated TraceIR.

Although rerunning the `Rikerfile` might seem to imply

that the entire build will run again, this is not the case. When `Rikerfile` launches `gcc`, RIKER lets the execution proceed (also under tracing) because `gcc`'s arguments, which now include `z.c`, also change. However, RIKER *skips* execution of the commands labeled A, C, D, and F in Figure 1, emulating them from the trace instead.

Command skipping. Let us examine the first command that RIKER skips, the instance of `cc1` labeled A in Figure 1:

```
1 cc1_1 = Launch(gcc_0, "cc1 x -o tmp.s", [...])
2 r71 = PathRef(cc1_1, CWD, "x.c", r--)
3 ExpectResult(cc1_1, r71, SUCCESS)
4 MatchMetadata(cc1_1, r71,
  [uid=100, gid=100, type=file, perms=rw-rw-r--])
5 MatchContent(cc1_1, r71,
  [mtime=1619457130, hash=3c6ea, cached=false])
6 r75 = PathRef(cc1_1, r3, "tmp.s",
  -w- truncate create (rw-rw-rw-))
7 ExpectResult(cc1_1, r75, SUCCESS)
8 UpdateContent(cc1_1, r75, [hash=054521])
```

The key observation is that emulation of this command's transcript—which RIKER always does before concluding that a command must run—detects no changes. `cc1` reads `x.c` (lines 4–5) and writes to a temporary file, `tmp.s` (lines 6–8). The file `x.c` is unchanged. Although `tmp.s` was created by `gcc` and is reused by every `cc1` process started by `gcc`, there is no dependency on that file's content because `cc1` truncates the file without reading it (line 6). Because RIKER detects no changes, it can emulate rather than execute `cc1`. Similar reasoning allows RIKER to skip C, D, and F.

Scenario 3: Making an inconsequential change. Suppose a comment is added to `x.c` and the build is run again. This change has no effect on the final compiled program and an ideal build system should do almost nothing. Referring again to the previous trace, RIKER detects a change (line 5) for `cc1` because `x.c` changes. However, RIKER correctly halts the build without ever running `as`, `collect2`, or `ld`.

Here is an excerpt of the `as` command's transcript:

```
1 as_1 = Launch(gcc_0, [as -o tmp1.o], [...])
2 r26 = PathRef(as_1, r3, "tmp1.o",
  rw- truncate create (rw-rw-rw-))
3 ExpectResult(as_1, r26, SUCCESS)
4 r27 = PathRef(as_1, r3, "tmp.s", r--)
5 ExpectResult(as_1, r27, SUCCESS)
6 MatchMetadata(as_1, r27, [uid=100,
  gid=100, type=file, perms=rw-----])
7 MatchContent(as_1, r27, [mtime=1619458806,
  hash=10732f, cached=true])
8 UpdateContent(as_1, r26, [mtime=1619458806,
  hash=3814e7, cached=true])
```

The `as` command reads `tmp.s` and writes to `tmp1.o`. RIKER concludes that `cc1`'s output `tmp.s` is unchanged (lines 6–7), even though the `mtime` is different. In RIKER, `mtimes` provide a fast path for change detection: a file's content is unchanged if its `mtime` is unchanged, or if its content produces the expected hash. Finally, we see `as` writes to `tmp.o` (line 8). Because `as` is unchanged, RIKER can instead restore the `tmp.o` file from its cache and skip `as`.

3.2 Summary

RIKER runs efficient incremental builds from simple specifications, even those with a single command. Throughout this section we never once needed to change the `Rikerfile`, even though the build's dependencies changed with the addition of new files; RIKER always ensures that incremental rebuilds produce the same effect as full builds. Finally, RIKER is language agnostic: it can be used to build programs written in any language using any executable build specification.

4 Tracing and TraceIR

This section defines terms that we use to describe RIKER's operation, describes RIKER's system call tracing mechanism, and introduces the novel TraceIR language that RIKER uses to record dependency information.

4.1 Definitions

An *artifact* represents system state such as a file, a directory, or a pipe. A *version* represents an artifact's state at a point in time during the build. Every artifact has both content and metadata versions. Two content versions are *identical* if and only if they contain the same bits. Two metadata versions are identical if and only if their permission bits and ownership are the same.

A *command* is a program that accesses or modifies artifacts, and may launch additional commands. A *dependency* is any version made visible to a command through a system call. A command is *changed* if its dependencies are not identical to the versions observed during the previous run, or if the outcome of an operation like path resolution differs from what was observed during the previous build (e.g. a file referenced during the last build no longer exists).

Versions are *equivalent* if they are identical, or if they could be written to the same artifact by two executions of a non-deterministic command given equivalent inputs. Outputs from different executions of a command given equivalent inputs are interchangeable, even if those outputs are not identical.

A *build specification* is any program that encodes a sequence of commands to run. A *build system* is a program that evaluates a build specification to perform a *build*. A *full build* executes all of the commands in the specification, while an *incremental build* produces the same effect while executing only a subset of commands.

When executing a command, RIKER records the dependencies and effects of each command in the TraceIR language. RIKER evaluates recorded TraceIR on subsequent builds to determine whether the command has changed. A command can be *skipped* if it is unchanged, otherwise it must be *executed*.

4.2 Tracing Implementation

RIKER executes commands under system call tracing to gather a complete set of dependencies. RIKER uses `ptrace` [17] to intercept system calls. Only calls related

to filesystem interaction, file descriptor management, and process creation—75 system calls in total—matter for dependency tracking. RIKER combines `ptrace` with `seccomp-BPF` [25] filters to avoid tracing irrelevant system calls. Nevertheless, tracing has high overhead even with filtering. To reduce overhead, RIKER injects a shared library into each build command to intercept calls to frequently-used `libc` system call wrappers like `open` and `stat` without incurring `ptrace` overhead. This approach is inspired by RR [24], with additional support for passing system call arguments through shared memory. For a build of `memcached`—a typical C project built with `gcc`—RIKER's injected library handles 95% of system calls (`ptrace` handles the remaining 5%). For `memcached`, shared library tracing reduces RIKER's full-build overhead from 1.81s (16.9%) to just 0.84s (7.8%) with no loss of tracing precision.

The next section describes the TraceIR language. Section 4.4 shows how system calls are translated to TraceIR.

4.3 The TraceIR Language

TraceIR is an executable, linear representation of a build's behavior. RIKER generates TraceIR from system call traces, and detects changes by evaluating TraceIR against a model of the filesystem. The TraceIR language describes the dependencies that are visible to each command during the build, as well as the side effects of each command's execution.

Design considerations. The design of TraceIR is guided by three important requirements. First, tracing must be *complete*, capturing dependencies on all artifacts. A missed dependency could lead to an incorrect build. Second, TraceIR records events *serially*, even if those events come from processes that run in parallel during the build. Recording events serially imposes a temporal ordering [15] on filesystem interactions. A temporal ordering makes the relationship between an access of an artifact and its corresponding version unambiguous at any given point in a build, even when that artifact is read and written concurrently. Finally, a TraceIR program represents *a single observed path of execution* for a command. If a command's dependency changes, RIKER will execute and trace the command to discover its new behavior.

Language elements. Table 2 shows the datatypes of the TraceIR language, and Table 3 shows nearly all of the statements in the TraceIR language. We omit three low-level operations for clarity. Return types are `BOOL` where omitted. A TraceIR program is a sequence of statements, each associated with a command *c*. Statements fall into four logical groups:

Artifact accesses establish a reference to an artifact. A reference can resolve successfully or result in an error. Some accesses are side effecting (e.g. to capture the behavior of `open` with the `O_CREAT` flag).

State checks record the state observed by a command *c* the last time it executed. If a state check fails, *c* observes a change and must re-execute.

| TraceIR Data Types | |
|--------------------|---------------------------------------|
| BOOL, INT, STRING | Normal primitive types |
| [T] | A list of elements of type T |
| OUTCOME | Success or a POSIX error code |
| REF | Reference to an artifact or OUTCOME |
| CMD | A build command |
| FLAGS | Flags associated with a file access |
| METADATAVERSION | An artifact's metadata |
| CONTENTVERSION | An artifact's content |
| SPECIALREFID | A special artifact ID: ROOT, CWD, ... |

Table 2: TraceIR data types.

State updates record the effect a command had on global state, such as writes to file content or metadata, or the creation and removal of directory entries.

Command updates record command creation, termination, and when a command waits for another to exit. These statements capture the semantics of `execve`, `exit`, `wait`, and related system calls.

4.4 Generating TraceIR Transcripts

RIKER translates each traced system call to a sequence of TraceIR statements called a *transcript*. The transcript below is generated when command *c* issues a successful `stat("input", &statbuf)` call.

```

1 r1 = SpecialRef(c, CWD)
2 r2 = PathRef(c, r1, "input", ---)
3 ExpectResult(c, r2, SUCCESS)
4 MatchMetadata(c, r2, [uid=100, gid=100,
   type=file, perms=rw-r--r--])

```

Line 1 is a reference to the command's current working directory. Line 2 uses the reference to resolve the path to the file `input`. This `stat` call did not include any special flags so the fourth parameter is `---`. If the file were opened rather than `stated`, this field would request read and/or write permission. For `lstat`, a `nofollow` flag would signal that path resolution should not follow symbolic links.

Because `stat` succeeds, line 3 records a successful outcome. If `input` is removed before a future rebuild, the observed result will be `ENOENT` and RIKER will detect a change. Finally, because *c* observes `input`'s metadata, line 4 records the observed metadata. If the file's metadata is modified, a rebuild will detect a change.

Importantly, TraceIR also records anti-dependencies. Supposing the `stat` call originally failed with `ENOENT`, the generated TraceIR would have had the same first two lines, but line 3 would expect `ENOENT` and line 4 would be omitted. If `input` is present on rebuild, RIKER would observe that the result is not `ENOENT` and would detect a change.

5 Build Algorithm

The RIKER algorithm, shown in Figure 2, performs two tasks: it detects changes and updates the build by running commands affected by those changes. RIKER's build algorithm

| TraceIR Statements | |
|--------------------|--|
| Artifact Access | <code>PATHREF (c : CMD, b : REF, p : STRING, f : FLAGS) : REF</code> Command <i>c</i> resolves path <i>p</i> relative to <i>b</i> with flags <i>f</i> |
| | <code>SPECIALREF (c : CMD, id : SPECIALREFID) : REF</code> Command <i>c</i> references a special artifact (e.g. <code>/</code> , <code>cwd</code>) |
| | <code>FILEREF (c : CMD) : REF</code> <code>DIRREF (c : CMD) : REF</code> <code>PIPEREF (c : CMD) : REF, REF</code> <code>SYMLINKREF (c : CMD) : REF</code> Command <i>c</i> references new anonymous file, directory, etc. |
| | <code>EXPECTRESULT (c : CMD, r : REF, e : OUTCOME)</code> Command <i>c</i> expects <i>r</i> to resolve with outcome <i>e</i> |
| State Checks | <code>MATCHMETADATA (c : CMD, r : REF, e : METADATAVERSION)</code> <code>MATCHCONTENT (c : CMD, r : REF, e : CONTENTVERSION)</code> Command <i>c</i> expects <i>r</i> to have metadata or content <i>e</i> |
| | <code>EXITRESULT (c : CMD, child : CMD, n : INT)</code> Command <i>c</i> expects <i>child</i> to have exit code <i>n</i> |
| State Updates | <code>UPDATEMETADATA (c : CMD, r : REF, v : METADATAVERSION)</code> <code>UPDATECONTENT (c : CMD, r : REF, v : CONTENTVERSION)</code> Command <i>c</i> updates <i>r</i> with metadata or content <i>v</i> |
| | <code>ADDIRENTRY (c : CMD, d : REF, e : STRING, a : REF)</code> Command <i>c</i> links artifact <i>a</i> as entry <i>e</i> in directory <i>d</i> |
| | <code>REMOVEDIRENTRY (c : CMD, d : REF, e : STRING)</code> Command <i>c</i> removes entry <i>e</i> from directory <i>d</i> |
| Command Updates | <code>LAUNCH (c : CMD, cmd : [STRING], rs : [REF]) : CMD</code> Command <i>c</i> launches child <i>cmd</i> with inherited references <i>rs</i> |
| | <code>JOIN (c : CMD, child : CMD)</code> Command <i>c</i> waits for child <i>child</i> to exit |
| | <code>EXIT (c : CMD, n : INT)</code> Command <i>c</i> exits with status <i>n</i> |

Table 3: TraceIR Statements.

is always guided by a saved transcript. RIKER's fixed-point build algorithm repeatedly evaluates the build transcript, running changed commands while checking for changes made visible to other commands. The build terminates when no new changes are found.

Changes. TraceIR statements are predicates that express expectations about state at specific points during the build. An expectation can be in regard to the outcome of path resolution, the exit code of a child command, or the content or metadata of artifacts. Predicates are checked against the the filesystem model *M*. This model, a set of artifacts, records the effects of any prior TraceIR statements. The model is lazily populated with actual filesystem state; predicates that refer to artifacts that have not been modified during the build are checked against actual filesystem state. When a command's TraceIR predicate fails—that is, the expected state does not match the model *M*—the command is changed and must execute to update the build.

Phases. RIKER's build algorithm runs in *phases*. Each phase is an evaluation of an entire TraceIR build transcript *T* in the context of the model *M*. Trace evaluation, carried out by `EVALTRACE` (line 6 of `DOBUILD`), is repeated until the set of commands that must run, *R*, is empty.

```

DOBUILD(trpath)
1  i = 1, M = { }, R = { }
2  T = LOADTRACE(trpath)
3  if |T|==0 then T = { LAUNCH (rkr, Rikerfile, ...) }
4  repeat
5      M = { }
6      (M, T, D, R) = EVALTRACE(M, T, R, false)
7      R = PLAN(D, R)
8      i = i + 1
9  until |R|==0
10 SYNCALL (M)
11 if i > 1
12     (–, T, –) = EVALTRACE(M, T, R, true)
13 WRIETRACE(T)

EVALTRACE(M, T, R, post)
1  T' = nil, D = { }
2  Rbuild = { }, Rpost = { }
3  for t in T
4      c = CMDOF(t)
5      if c ∉ R
6          (ts, M, D, δbuild, δpost) = EVALSTMT(t, M, R, D, post)
7          if δbuild then Rbuild = Rbuild ∪ {c}
8          if δpost then Rpost = Rpost ∪ {c}
9          T' = T' @ ts
10 return (M, T', D, Rbuild ∩ Rpost)

```

Figure 2: RIKER’s build algorithm. DOBUILD repeatedly evaluates a TraceIR build transcript *T* in the model *M* until it observes no new changes. EVALTRACE evaluates a single pass through *T*, returning an updated model and trace, command dependence graph *D*, and set of commands that must run, *R*. @ concatenates two lists. At the end of the repeat-until loop, the build is up-to-date.

Emulation vs. Execution. RIKER performs incremental builds by mixing execution and emulation of build commands. RIKER *emulates* a command by evaluating its TraceIR to update the in-memory model *M*, but does not run the command. RIKER *executes* a command by running it with `exec(3)`. RIKER traces the system calls of the executing command to generate new TraceIR, and evaluates this new TraceIR to keep the in-memory model *M* in sync with filesystem state. Whether a command is emulated or executed depends on whether it was added to *R* during a previous phase (see §5.1).

Invariant. RIKER enforces the invariant that any command whose dependencies have changed will be executed; failing to do so results in an incorrect build. RIKER emulates all other commands instead of executing them.

Executing an unchanged command preserves correctness, but doing so is costly. We avoid unnecessary command executions whenever possible because they take orders of magnitude longer than emulating a command to recreate its effects. For example, when a command’s output is missing the file can be restored from a cached copy (see §5.2) instead of executing the command to recreate the file. We discuss the correctness of this approach in Section 5.5.

To avoid over-approximating *R* (the set of commands that will run) RIKER evaluates the build transcript *T* repeatedly (line 4). Repeated evaluation is necessary because change detection is a dynamic problem [5]. For example, suppose *T* contains two commands, *A* and *B*, and that *B* reads one of *A*’s outputs. Suppose *A* must run; does *B* need to run? The answer is “maybe.” If *A* produces the same output that it produced previously, then *B* does not need to run. We saw this exact situation in the overview’s example when adding a comment to a source file. It is safe to conservatively run *B* any time *A* runs, but RIKER can potentially save work by deferring the decision to run *B* until after *A*’s effects are observed.

Statement evaluation. At the heart of the build algorithm is the evaluation of TraceIR statements. The purpose of evaluating a statement is twofold: to update state and to detect changes. When a command is emulated, the only state updated is *M*. When a command is executed, both *M* and the actual filesystem are updated. The semantics of change detection depend on the specific TraceIR statement (see §4.3).

EVALSTMT (line 6) evaluates a TraceIR statement. Evaluation returns one or more TraceIR statements, an updated model *M*, a command dependence map *D* (see §5.3), and two flags denoting whether the statement observed a change, either a build or post-build change (see **Post-build checks** below). The returned trace statements are used in the next build phase. When a command is emulated, its trace steps are simply echoed back. We describe command execution in §5.1. After a transcript is evaluated, RIKER calls PLAN (line 7), which may mark extra commands to run (see §5.3).

Filesystem and model. RIKER begins each phase by initializing the model *M* (line 5 in DOBUILD). Emulated updates are discarded after each phase because those updates are replayed in subsequent phases, whereas changes resulting from execution are written directly to the filesystem. SYNCALL (line 10 of DOBUILD) writes all changes in the model *M* to the filesystem at the end of the build. This operation ensures the outputs from commands that did not need to run are written to disk.

Post-build checks. Desirable state left behind from a previous build can look like a change to a command run in an early part of a build. RIKER finishes every build with a series of *post-build checks* to avoid doing unnecessary work in this scenario. To illustrate, recall our working example from section 3 which runs the command `gcc -o program *.c`. Before performing any compilation steps, `gcc` will stat the `program` file, which does not yet exist. The `stat` system call produces the following TraceIR:

```

1  r8 = PathRef(gcc_0, CWD, "program", ---)
2  ExpectResult(gcc_0, r8, ENOENT)

```

Later in the build, `program` is created by the linker. As a result, immediately running the build again after completing the first full build would detect a change on line 2, and `gcc` would run. However, running `gcc` is unnecessary because the observed change is a byproduct of the build itself. Post-build

checks enable RIKER to skip over these changes by encoding multiple justifications to skip: a command is unchanged if all of its predicates match what was observed during the build, or if the predicates match state found *immediately after* the conclusion of the build.

The post-build phase (line 12 of DOBUILD) emulates all commands in T , but adds additional predicates to check post-build state. After running the post-build phase in the example build, the above TraceIR excerpt is extended to capture either outcome of the `stat` call:

```
1 r8 = PathRef(gcc_0, CWD, "program", ---)
2 ExpectResult(gcc_0, r8, ENOENT) [build]
3 ExpectResult(gcc_0, r8, SUCCESS) [post-build]
```

The predicate on line 2 is the same as before, but has been marked as a *build* predicate. The new predicate on line 3 describes an alternative. With post-build checks, a command is only changed if its predicates fail in both the *build* and *post-build* scenarios (line 10 of EVALTRACE). In other words, a command is changed only when its dependencies are distinct from both the dependencies observed during the last build and immediately after the last build.

5.1 Command Emulation and Execution

RIKER begins every build by emulating a *root command*. The root command sets up initial references (e.g. the root directory, working directory, standard streams, etc.) and then launches `Rikerfile`. When an emulated command contains a LAUNCH statement, RIKER will either emulate or execute the child command depending on whether or not the child is in R . If the child is in R RIKER will launch the command in a new process with system call tracing. All statements from the child command are discarded from the transcript, and will be replaced with new TraceIR collected from the child's execution. If c is not in R , RIKER simply emulates the child from the build transcript.

Parent commands typically wait for their children to exit using the `wait` system call; this system call generates a JOIN statement in the build transcript. RIKER emulates a JOIN statement by handling traced system calls from build processes until the child command's main process exits.

When a command c is executed it may depend on artifacts modified by emulated commands. The latest state of these artifacts is in M , not on the actual filesystem. RIKER will write these changes out to the filesystem as they are needed, either when c begins execution (when file descriptors are inherited by the child) or when c first accesses the artifact during its execution. This mechanism is critical for RIKER's ability to incrementalize builds, and relies heavily on caching.

5.2 Caching

Without caching, RIKER's ability to execute sub-commands in isolation would be limited because many of the needed inputs would not be available. `gcc` and other language tools routinely create "ephemeral" state—like temporary files—

communication channels for tools in the toolchain. RIKER's caching and TraceIR make it possible to automatically restore this ephemeral state to run a command whose inputs are produced by other commands (e.g. the assembler or linker).

The motivating example in Figure 1 illustrates this functionality. Suppose a user edits `main.c`; RIKER will execute the compiler and assembler to produce `tmp2.o`, but does not need to execute any commands to produce the other `.o` files. Instead, these files are simply restored from cache when they are first accessed by the linker. The fact that `gcc` reuses `tmp.s` is not a problem, as each use of the file is ordered in the build transcript so RIKER always knows which version of the file is required for every command.

RIKER caches files, symlinks, and directories. Cached artifacts are stored in a `.rkr` directory, and are garbage collected when RIKER detects that they are no longer referenced by the build transcript. RIKER currently does not cache pipes, sockets, or special files. If a command that reads from a pipe must run, RIKER will also run commands that write to that pipe to provide uncached inputs.

5.3 Build Planning

The purpose of build planning (line 7 in DOBUILD of Figure 2) is twofold: to ensure the build terminates, and to improve efficiency. PLAN works much like the mark-sweep garbage collection algorithm [18] and uses the command dependence graph, D , returned by EVALTRACE. D is a digraph of producer-consumer relationships between commands.

Commands are marked under a few conditions: a) a command is in R , having directly observed a change in EVALTRACE; b) a command consumes uncached input produced by a command already marked to run; c) a command produces uncached output consumed by another command already marked to run; or d) a command produces uncached output that should persist after the build.

The above criteria identify commands that subsequent build phases in a cycle-free build would eventually identify, so for those builds it reduces the number of phases. However, in builds with dependence cycles, RIKER may not terminate without special handling. In D , a cycle appears as a strongly-connected component (SCC) [31]. Planning ensures that commands in a cycle run atomically. Caching also breaks cycles; RIKER only needs to atomically run SCCs that interact through uncached artifacts like pipes.

5.4 Exit Code Handling

Unlike prior forward build systems, RIKER can execute a sub-command without executing its parent. Parent commands can observe the exit codes of their children, so if a child finishes with a different exit code the parent must run. Because exit code changes are rare, RIKER optimistically assumes that the child's exit code will not change. In the common case the child command runs, finishes with the expected exit code, and the build is complete. If the child finishes with a different

exit code, the parent observes a change and will re-execute in the next phase of the build. Executing the parent may re-execute the child if the child's dependencies change again. In the worst case, RIKER could backtrack on every command, taking $O(n^2)$ time, where n is the number of commands. Even for builds that contain compilation errors—and thus changed exit codes—we observed that total work done is close to $O(n)$.

5.5 Correctness

Here we provide a proof sketch for the correctness of RIKER's incremental build algorithm. We make the following assumptions.

- A1. The user-provided full build specification does what the user intends.
- A2. The user accepts that equivalent outputs (defined in §4.1) are interchangeable, an assumption shared by most build systems.
- A3. Intercepting system calls is sufficient to determine all dependencies.
- A4. Our translation from system calls to TraceIR faithfully captures dependencies and side-effects. Our empirical evaluation in Section 6 provides evidence that this translation is accurate.

An incremental build tool that produces outputs that could not have come from a full build is clearly incorrect. A *consistent* build produces output that could have come from a full build, and is therefore correct (A1, A2) [12, 13].

Running an empty build specification produces no output, so all rebuilds of this specification are by definition consistent. Given a consistent build with k commands, add command $k + 1$ to the specification. Command $k + 1$ may depend on outputs from any of the preceding k commands. The build remains consistent when $k + 1$ is executed (A1). On rebuild, if $k + 1$ is unchanged, skipping command $k + 1$ preserves consistency because RIKER restores cached artifacts (A2). By induction, a build is consistent as long as all changed commands are executed.

RIKER executes changed commands in phases. If an executed command produces a different output read by another command, the latter command is changed and will execute in the next phase. The build terminates when a phase finishes with no changed commands. Since RIKER's algorithm executes all changed commands, it produces consistent builds.

The proof sketch above assumes commands k and j do not participate in a dependence cycle, but these cycles arise in real builds. Without loss of generality, assume k writes output that j accesses, and later j writes output that k accesses; RIKER's build transcript captures the temporal order of these interactions. We allow for such cycles by logically partitioning k into k' , the portion of k that runs before its dependence on j , and k'' , the remainder of k . Now j depends on k' and k'' depends on j , so there is no longer a cycle. We add the constraint that if either k' or k'' must run, both will run, as these are actually two parts of the same command.

6 Evaluation

Our evaluation of RIKER addresses four key questions:

- Q1: Are RIKER builds easy to specify?
- Q2: Are RIKER builds fast?
- Q3: Are RIKER builds correct?
- Q4: How does RIKER compare to RATTLE?

We use RIKER to build 14 software packages, including large projects like LLVM, memcached, redis, and protobuf. Evaluation was conducted on a typical developer workstation with an Intel Core i5-7600 processor, 8GB of RAM, and an SSD running Ubuntu 20.04 with kernel version 5.4.0-80. Builds use either gcc version 9.3.0 or clang 10.0.0.

6.1 Are RIKER builds easy to specify?

To answer this question, we wrote Rikerfiles for seven applications: lua, memcached, redis, rkr, sqlite, vim, and xz. The new builds produce the same targets as the projects' existing make or cmake builds. Unlike the default build systems, the RIKER-based builds do not list any dependencies or incremental build steps. Three of these builds were written by undergraduate students over the course of a few days; the students were new to RIKER and unfamiliar with the project sources they were building. The biggest challenge the students faced was understanding the existing build specifications, a task that is likely easier for the project's own developers.

A key feature of a Rikerfile is its brevity, illustrated by memcached's complete Rikerfile:

```
1 CFLAGS="..."
2 DEBUG_CFLAGS="..."
3 MEMCACHED_SRC="memcached.c hash.c ..."
4 TESTAPP_SRC="testapp.c util.c ..."
5 gcc $CFLAGS -o memcached $MEMCACHED_SRC -levent
6 gcc $DEBUG_CFLAGS -o memcached-debug \
7   $MEMCACHED_SRC -levent
8 gcc $CFLAGS -o sizes sizes.c -levent
9 gcc $CFLAGS -o testapp $TESTAPP_SRC -levent
10 gcc $CFLAGS -o timedrun timedrun.c -levent
```

This level of simplification is typical; Our largest Rikerfile—used to build sqlite—is just over 5KB, and consists mostly of a list of source files. Forward builds are easier to specify because of automatic dependency discovery. RIKER's incremental builds are also significantly shorter than specifications for prior forward build tools (see §6.4).

6.2 Are RIKER builds fast?

The first full build of any software project is usually the longest build. Full builds are where RIKER incurs the largest absolute overhead. Importantly, full builds are not the common case; developers run incremental builds far more often than full builds. This section shows that even with the extra delay, full builds are reasonably fast with RIKER.

To measure RIKER's overhead, we built 14 software projects with RIKER. Seven of these projects use a Rikerfile that replaces the default build (see §6.1), while

Figure 3: RIKER runtime overhead for full builds compared to each project’s default build system. RIKER’s median overhead on full builds is 8.8%, with a median absolute slowdown of 1.2s.

the other half use a `Rikerfile` that *wraps* the default build. The only requirement for a `Rikerfile` is that it run a full build, so a `make`-based project can be built with a one-line `Rikerfile`: `make --always-make`. Unfortunately, tracing `make` itself can lead to spurious dependencies so this approach is only suitable for evaluating full-build performance.

Figure 3 shows the results of running full builds with RIKER. These builds are run in serial; we examine the performance of parallel builds later in this section. Each project is built five times with RIKER and its default build system, with the exception of LLVM which we build three times due to its long build time. Median full-build overhead for all benchmarks is just 8.8%; most builds have between 4% and 20% overhead. TraceIR transcript sizes are roughly proportional to build time, ranging from 2MB for `autoconf` (1.2s build) to 264MB for LLVM (77-minute build). In absolute terms, RIKER spends a median of just 1.2 seconds longer to perform a full build than each project’s default build system. The longest additional waiting time for a RIKER build is for LLVM, which takes about three minutes longer than the default 77 minute build (4% overhead). The worst overheads appear in projects like `autoconf` and `coreutils` that build many small programs rather than a single large executable. RIKER’s full-build overhead is less than 25% for all other projects.

Incremental Builds. The most important measure of efficiency for a build system is its ability to perform fast incremental rebuilds. We perform two experiments to measure the efficiency of RIKER’s incremental builds.

First, we measure the time it takes RIKER to perform a *no-op build*—one where no commands need to run—by running an incremental build immediately after finishing a full build. The median RIKER no-op build time over the 14 benchmarks is just 220ms, compared to 5ms for the default build system. The longest additional wait is for the LLVM build, which takes 11.3s with RIKER compared to 4.8s with `make`. More than half of the no-op builds with RIKER take just 162ms longer than the default build system, an imperceptible difference.

Second, we use real developer commits to measure the efficiency of performing incremental builds with RIKER versus a project’s default build system. We run this experiment on six projects—`memcached`, `redis`, `rkr`, `sqlite`, `vim`, and `xz`—all of which have custom `Rikerfiles` and public version control

Figure 4: Time to run 100 incremental builds as a percentage of the time to run a full build at every commit using the project’s default build system. Excluding `sqlite`, RIKER’s incremental builds save 235 minutes compared to 250 minutes saved by the default build system.

histories. We perform a full build of each project, and then measure the time required to update the build at each of the next 100 commits in the project’s `git` repository. This experiment simulates a developer performing incremental builds after editing a subset of the project’s source files.

Figure 4 shows the results of this second experiment. The graph shows the total time required for all 100 incremental builds as a percentage of the time it would take to run a full build at each commit. Note that we compare RIKER’s incremental build times to the time it would take to run a full build with the project’s *default* build system. This ensures RIKER’s overhead on the full build does not give it an advantage compared to the slightly faster default build system.

95% of RIKER’s incremental builds complete within 3.8s of the default build system. In every benchmark except one (`sqlite`), RIKER is able to reduce build time by at least 63% relative to a full build. Over 5000 incremental builds of these five benchmarks, the default build system reduces build time by 74.7%, saving 250 minutes compared to full builds at each commit. RIKER saves 70.1% of total build time—a total of 235 minutes. Building with RIKER yields 94% of the benefit of a manually-specified incremental build, but with *no manual effort* and *no risk of errors*.

RIKER is able to save more time than the default build system for `memcached` because the case study includes several commits that edit the build specification itself. These edits generally require a full build for `make`-based projects, but RIKER is still able to perform a safe incremental build when the specification changes.

Neither RIKER nor `make` saves any work when building `sqlite`. This is because `sqlite`’s build concatenates all of its source files together before compiling them so the project can be distributed as a single source file. RIKER’s overhead adds less than three seconds (4.2%) to each “incremental” build.

Parallel Builds. Our evaluation has so far focused on serial builds, but parallel builds are also a useful mechanism for reducing build times. There are two concerns when it comes to RIKER’s support for parallel builds. First is scalability: how does RIKER’s tracing impact the performance of parallel builds? The second concern is expressiveness: how do users write a `Rikerfile` that describes a parallel build?

To assess RIKER’s scalability we focus on LLVM, our largest benchmark. On our evaluation machine, which has four cores, we see good scalability when adding up to four parallel jobs to LLVM’s `make` build. Build time is reduced by 54.3%, 64.4%, and 71.9% when building with two, three, and four workers respectively. With RIKER, we see reductions in build time of 47.7%, 63.0%, and 67.0% for the same numbers of workers. RIKER’s overhead increases from 4.0% for the serial build to 22.2% with four workers. A likely cause for this reduction in scalability is that RIKER utilizes a busy-wait loop that monopolizes a core. Even with this limitation—which we plan to address—parallel builds with RIKER are still significantly faster than serial builds.

While the prior experiment examines RIKER’s tracing performance on a parallel `make` build, it is also possible to write parallel build specifications directly in a `Rikerfile`. To make this as easy as possible, RIKER includes a wrapper around common C/C++ compilers that launches sub-commands for compilation in parallel, which is always safe (two `.c` files can always be compiled simultaneously). With RIKER’s compiler wrapper, simple lines like `gcc *.c` start parallel compilation tasks for each source file, which RIKER can also run in parallel for later rebuilds. Enabling this wrapper reduces build time for `memcached` by about 50%, compared to 60% with `memcached`’s own parallel `make` build. RIKER’s compiler wrapper provides an easy, automatic way to run parallel builds, and RIKER’s tracing does not significantly limit scalability.

6.3 Are RIKER builds correct?

We run each project’s full test suite for both the default and RIKER builds. For the six projects in the previous section, the tested outputs are the product of one full build and 100 incremental builds, one for each commit. The remaining projects run only full builds. Every RIKER project passes exactly the same tests as the original build system. This experiment provides evidence that RIKER correctly updates builds to produce equivalent final targets.

We have additional confidence that RIKER’s translation from system calls to TraceIR and its POSIX filesystem model are correct because RIKER checks the outcomes of operations in the model against actual system call results. RIKER raises a warning if the model deviates from actual system behavior; our experiments and test suite raise no such warnings.

6.4 How does RIKER compare to RATTLE?

To compare against the prior state of the art forward build system, we ported the `memcached` build to RATTLE [23]. Our efforts to port other benchmarks to RATTLE were not successful. RATTLE limits state modeling to files, meaning RATTLE misses some kinds of changes [29, 30]. We demonstrate with the following RATTLE build:

```
main :: IO ()
main = rattleRun rattleOptions $ do
  cmd "gcc prog.c"
```

```
cmd "mkdir dir"
cmd "mv a.out dir"
```

The full build runs correctly. However, because RATTLE does not model directories, changing `prog.c` leads to an inconsistent rebuild. A new `a.out` is placed in the current directory, leaving the original in `dir` untouched. RATTLE cannot build `sqlite` for precisely this reason. RATTLE also does not handle circular dependencies. The `lua` build calls `ranlib`, which is used to create library archives. Since `ranlib` modifies its input, RATTLE fails during the full build.

We were able to build `memcached` with RATTLE, which imposes a median overhead of less than 1% for the full build. This is because RATTLE uses library interposition for tracing, which is faster than `ptrace` but will miss system calls not issued by `libc`. A straightforward translation of the build specification from RIKER to RATTLE does *not* result in good incremental build performance; RATTLE cannot run fine-grained incremental builds from simple specifications, so it only reduces build time by 25% compared to full builds over the 100 commits from our earlier experiment. This is significantly less than the 78% build time reduction RIKER is able to achieve from the simple build specification. A RATTLE specification with comparable incremental build performance requires 63 separate commands, compared to just five for RIKER.

7 Conclusion

RIKER significantly lowers the burden of correctly specifying fast incremental builds. A RIKER build specification can be any executable program, like a simple shell script that performs a full build. In many cases, even a single build command such as `gcc *.c` is sufficient. Users do not need to list dependencies in their build specifications, nor are they required to break builds into incremental steps. Nevertheless, RIKER always builds correctly and quickly.

RIKER uses low-overhead system call tracing to automatically discover dependencies as build commands execute, and on rebuild, runs only the subset of commands required to bring the build up-to-date. RIKER has a median overhead of 8.8% across 14 real software packages, and it realizes 94% of `make`’s incremental build speedup with no manual effort and no risk of errors. We think these substantial engineering improvements are well worth RIKER’s modest overheads. RIKER is available under an open-source license at <https://rkr.sh>.

A Artifact Appendix

Abstract

The RIKER artifact includes a virtual machine image with a pre-installed copy of RIKER. RIKER is a build system that automatically discovers and runs incremental builds from simple specifications. This artifact makes it easy to reproduce the experiments described in the paper, which evaluate RIKER’s performance and effectiveness as a build tool.

Scope

This artifact should be used for two purposes: a) to reproduce the experiments from the paper, and b) to generate plots from the new results. The provided scripts reproduce the full-build overhead plot (Figure 3), the incremental savings plot (Figure 4), and the summary statistics reported in the abstract and in Section 6. We expect runtime overhead numbers will vary across platforms. Running the evaluation within a virtual machine will also likely have some effect on overhead. However, the artifact’s overhead should be close to the paper’s reported 8.8% median overhead on full builds, and incremental savings should be close to `make`’s incremental build performance.

Contents

README: A detailed guide to setting up the artifact and running experiments from the paper.

Virtual Machine Image: A VM image in OVA format that contains RIKER’s source code, build dependencies, and scripts that automatically run the paper’s benchmarks.

Hosting

The artifact is available at <https://doi.org/10.5281/zenodo.6544966>. Updated versions of RIKER will be available at <https://rkr.sh>. We recommend using the updated version for uses other than reproducing experimental results from the paper. Newer versions are likely to be more stable, support more kernel versions and architectures, and include bug fixes and additional features.

Requirements

Hardware Requirements. The virtual machine included with this artifact requires an x86_64 machine.

Software Requirements. The virtual machine image includes all build and evaluation dependencies. The OVA file can be imported into any hypervisor that supports OVA, but it was developed and tested using VirtualBox. The experimental evaluation requires network access; other hypervisors may require changes to network configuration after import.

FlatFS: Flatten Hierarchical File System Namespace on Non-volatile Memories

Abstract

The conventional file system provides a hierarchical namespace by structuring it as a directory tree. Tree-based namespace structure leads to inefficient file path walk and expensive namespace tree traversal, underutilizing ultra-low access latency and good sequential performance provided by non-volatile memory systems. This paper proposes FlatFS, a NVM file system that features a flat namespace architecture while provides a compatible hierarchical namespace view. FlatFS incorporates three novel techniques: coordinated file path walk model, range-optimized NVM-friendly B^r tree, and write-optimized compressed index key layout, to fully exploit flat namespace structure to improve file system namespace performance on high-performance NVMs. Evaluation results demonstrate that FlatFS achieves significant performance improvements for metadata-intensive benchmarks and real-world applications compared to other file systems.

1 Introduction

Large, deep directory tree stresses file system namespace performance. For example, Hive, a famous data warehousing software system, uses a column-based partition technique to provide efficient query for big database tables [39]. Every column value represents a path component, and all columns constitute a file path to index the data. Such a partition technique causes a large deep directory tree for a wide table, making data query prohibitively expensive.

The recent advent of ultra-fast non-volatile memories revolutionized file system design, shifting performance bottlenecks from hardware I/O to the software stack. However, the current file system namespace structure, which is designed for slow storage devices, encounters severe performance issues with high-performance non-volatile memory systems [1, 20, 30, 36].

The file system provides a hierarchical namespace that is structured as a directory tree [5, 37], as shown in Figure 1a. The virtual file system (VFS) unifies multiple volatile namespace hierarchies to provide a single global namespace

view [40]. For any metadata system calls, the VFS first performs a pathname lookup (i.e., path walk) by walking the directory tree to find the associated directory entry (dentry), and then performing metadata operations, e.g., changing file permissions. Hierarchical namespace structure causes two major performance problems: *inefficient file path walk* and *expensive namespace tree traversal*.

First, current file path walk is slow and non-scalable. Resolving a path component involves costly dentry search and other coupled system operations like security module enforcement [10, 23, 24, 40]. Moreover, suppose a file path contains n components, resolving the last component needs to locate previous $n - 1$ components. The total path walk task is linear to the number of components in the file path. The path walk efficiency has a slight performance impact on system calls for slow storage devices since hardware I/O dominates. In contrast, for NVMs offering ultra-low access latency [17, 42, 46], such high critical-path latency is unacceptable (see §2.1).

Second, traversing the namespace tree recursively is expensive with the hierarchical namespace structure. Entries of different directories are physically scattered over the storage device. It results in poor data access locality and indirect memory addressing during tree traversal. Namespace tree traversal is prevalent in common system usages such as *find*, *rm -r* and *ls -R*. Moreover, commercial NVMs like Intel Optane memory provide $> 5GB/s$ memory bandwidth and prefer sequential memory access behaviors [17, 46]. Unfortunately, hierarchical namespace structure fails to utilize this important system characteristic (see §2.2).

Research efforts have been devoted to addressing these two problems. Tsai et al. [40] propose full-path caching to reduce path walk latency in the VFS layer. Solaris also incorporates a similar path-to-vnode cache [23]. However, caching is heavily dependent on file access locality. ByVFS [41] bypasses the VFS directory tree and directly manipulates dentry from the file system. As NVM devices deliver unbalanced read/write performance, the dentry write performance is sub-optimal. A file system level optimization is utilizing efficient data structures (e.g., radix tree [44], hash table [15, 16], B^+

tree [5, 34, 37], skip list [13]) or key-value stores (e.g., LevelDB [2, 32] and TokuDB [6, 18]) to manage and index persistent directory entries. Though these data structures offer good indexing performance, the data locality problem is not well-addressed. Moreover, all existing in-kernel file systems are developed underneath the VFS framework [14, 18, 26, 31, 44, 48]. Therefore, pathname lookup performance in these file systems is constrained by VFS path walk efficiency.

This paper revisits namespace structure for ultra-fast, byte-addressable NVMs and proposes a novel file system named FlatFS. FlatFS exhibits a flat namespace architecture but still provides a compatible hierarchical namespace view. File metadata are directly indexed by their unique hierarchical paths. Hierarchical paths are organized without any further structure.

The flat namespace structure brings two performance advantages for file system design for NVMs. First, file path walk is fast and scalable as it only requires a single pathname lookup to flat namespace irrespective of path length. It effectively shortens the path walk for metadata system calls. Second, data locality is improved because contiguous directory entries in the namespace are also stored consecutively on the storage device. It accelerates file system namespace traversal and benefits directory range operations.

To exploit flat structure to improve namespace operation performance on high-performance NVMs, FlatFS incorporates three core techniques. First, a coordinated path walk is proposed to orchestrate two distinct path walk models in a global unified VFS namespace §4.1. FlatFS achieves fast, scalable path walk by separating pathname lookup from other intricate system operations, yet preserves the system semantics as the conventional path walk model. Instead of reconstructing the existing path walk module, coordinated path walk offers a flexible and backward-compatible solution to integrate a distinctive path walk model into the global namespace.

Second, a range-optimized NVM-friendly B^+ tree is devised to manage variable-sized index keys §4.2. B^+ tree provides efficient data-structure-level range operations (e.g., *range insert*) in logarithmic time. It effectively remedies the directory move shortcoming for the flat namespace, as well as facilitates designing other fast directory range operations §4.3.

Third, a write-optimized compressed (WoC) index key design is proposed by leveraging NVM byte-addressability to improve variable-sized key storage efficiency as well as reduce expensive small memory writes and data persistence overheads in key management on NVM systems §4.4.

Finally, FlatFS achieves low-cost metadata crash-consistency for the flat namespace §4.5. The WoC key design effectively reduces the performance costs for data consistency in index key insert and removal. For directory range operations that involve complex tree structure manipulation, FlatFS also simplifies namespace tree crash-safety design based on an insight derived from B^+ tree structure primitives.

We evaluate FlatFS with extensive experiments using both benchmarks and three applications (a version control system

Git, a parallel file indexer Psearchy [11], and a data warehouse software Hive [39]) on Intel Optane DC Persistent Memory §5. Evaluation results demonstrate that our flat namespace fully unleashes the high-performance NVM system. FlatFS outperforms other file systems by a factor of 4.02× for micro- and macro-benchmarks and improves metadata-intensive application performance by up to 37.5%.

In summary, this paper makes the following contributions:

- We analyze two performance issues in hierarchical namespace structure with high-performance NVMs.
- We propose a metadata-optimized file system FlatFS with three core techniques to flatten the hierarchical namespace for fast, byte-addressable NVM systems.
- We conduct extensive experiments to demonstrate the performance benefits of FlatFS to both metadata-intensive benchmarks and applications.

2 Background and Motivation

This section takes Linux kernel as an example to describe performance issues in the current file system namespace.

2.1 Inefficient File Path Walk

Costly component resolution. We conduct an experiment to demonstrate path component resolution inefficiency. We measure the execution latencies of six typical metadata system calls (*creat*, *open*, *stat*, *chmod*, *unlink*, *mkdir*) in NOVA file system on our testbed machine. Every system call operates on a file in a six-depth directory. Figure 1b shows the system call execution time and performance breakdown.

When the dentry cache (dcache) is hot, profiling results show that an average 15.87% execution time is spent on the dcache lookup. The dcache lookup includes filename hashing and hash table lookup. Currently, there is only a centralized dcache in the VFS layer. Increasing dentries stresses the dcache indexing performance. The permission checking takes 8.83% of the execution time on average. The path walk also spends 11.65% execution time on other system operations (denoted as *Other Walk* in Figure 1b), such as mount point checking and reference counter updating. In summary, when the dcache is hot, resolving a six-component file path occupies 14.17%-67.19% execution time for five system calls. The file operations take an average of 31.49% execution time.

On the other hand, when the dcache is cold, the underlying file system has to search the missing dentry. Dentry lookup of NOVA file system takes 69.26% of execution time for cold dcache. The dentry miss penalty is high. Besides the I/O transfer for the missing dentry, it also includes searching the dentry in the storage device and inserting this dentry into various VFS management data structures. Table 1 compares the block reading and dentry lookup latencies on NVM and SSD. Relatively slow SSD delivers long I/O latency, which dominates the overall execution latency. However, the dentry lookup time percentage increases around 20% when the storage device shifts from SSD to NVM. It indicates that

Figure 1: File System Namespace Structure in Linux and Performance Issues

Table 1: Comparing Block Read and Dentry Lookup Latency on NVM and SSD

| | SSD: block reading (%) | SSD: dentry lookup (%) | NVM: block reading (%) | NVM: dentry lookup (%) |
|------|------------------------|------------------------|------------------------|------------------------|
| Ext4 | 58.74% | 4.12% | 27.11% | 25.36% |
| XFS | 60.98% | 3.34% | 29.45% | 28.10% |

the performance bottleneck transfers from the hardware I/O latency to software path walk design with ultra-fast NVMs.

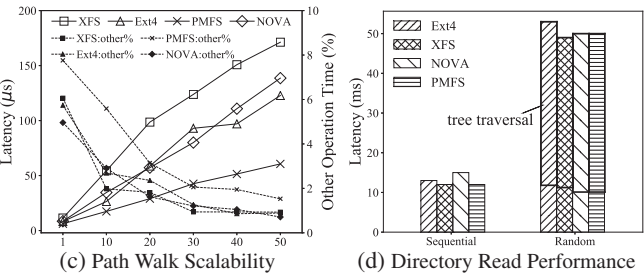

Non-scalable path walk. The current component-at-a-time path walk design is non-scalable with the number of path components. Such path walk design is widely adopted in current operating systems as it is convenient to implement the component resolution. Moreover, many other system functionalities are implemented upon component resolution [10, 24]. They further increase the latency and exacerbate the path walk scalability issue. In addition, it is difficult to decouple them from the path walk.

We perform an experiment to understand the path walk scalability problem. We measure the *stat* syscall latency with different path component numbers on four NVM file systems. The VFS dcache is cold in the experiment. As shown in Figure 1c, the *stat* execution latency of four file systems increases dramatically as path length increases. The operation latency of the 50-component file path is nearly 14× higher than the 1-component file path. The VFS invokes file system-specific *getattr* to retrieve the file attributes. However, *getattr* only takes 1.01% on average of four file systems for a 50-component path configuration (denoted as *FS:other%* in Figure 1c). The rest of the execution time is spent on resolving the lengthy file path.

Summary. Current slow, non-scalable file path walk design has a large impact on metadata system call performance. This is a common problem for all file systems running on different devices like SSDs or HDDs. However, as commercial NVM devices offer near-DRAM access latency, the major bottleneck shifts from long hardware I/O to software path walk design, motivating us to reduce such software latency.

2.2 Expensive Namespace Tree Traversal

Recent Intel Optane memory studies report that there is an asymmetry between sequential and random access performance [17, 28, 43, 46]. The performance gap between sequential and random memory bandwidth ranges from 2.3× to 3.5×. Moreover, the memory access latency is also sensitive to sequential and random access patterns [17, 42, 46].

File systems directly persist their directory tree in the NVM device. Traversing such a hierarchical namespace tree recursively is expensive. The reason is twofold. First, as directories logically form a tree structure, traversing the hierarchical tree causes indirect memory accesses. Second, persistent tree traversal introduces random memory access as dentries of different directories are distributed across the device. Previous studies show that both these memory access behaviors are suboptimal [17, 46]. Recursive tree traversal is an important namespace operation and used by many real-world applications heavily (e.g., *cp -r*, *git status*). Moreover, as page cache is removed from the NVM storage stack [26, 31, 44, 48], directory reading operations are directly performed on the NVM device. Existing persistent namespace tree traversal degrades directory reading performance.

We perform an experiment to understand the performance costs of hierarchical namespace tree traversal. We create two sets of 1024 files. Files in the first set are stored under an eleven-depth directory hierarchy. All files of the second set are stored in a one-depth directory. We use *ls -R* to read these two directories recursively. The first listing operation walks a hierarchical namespace and the second listing operation simulates sequential access in a flat namespace. Figure 1d shows that sequential directory reading performs 4.08× better than random directory reading. Traversing the hierarchical directory tree occupies nearly 80% total execution time.

Summary. The hierarchical namespace structure leads to low directory reading performance due to expensive tree traversal. As the page cache is removed from the modern NVM storage stack, directory reading operations access data stored on NVM devices directly. How to architect the file system namespace structure to exploit the device characteristic to improve the namespace operation performance still remains unsolved.

3 Overview

3.1 Design Goals

Through flattening the hierarchical namespace, we build a high-performance, POSIX-compliant NVM file system. In particular, we have four design goals.

- **Short path walk.** File path walk is essential for most of the metadata system calls. FlatFS aims to reduce such software latency to minimize performance impacts on system call execution.

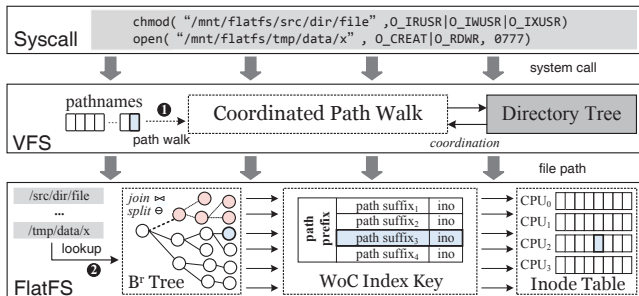

Figure 2: FlatFS System Architecture

- **Optimizing range operation.** As sequential accesses are optimal in NVMs, FlatFS aims to re-structure namespace architecture to fully exploit this system characteristic.
- **Reducing persistence costs.** FlatFS applies write-optimization techniques to key layout design to reduce data persistence costs in its index key management.
- **Ensuring namespace crash-safety.** FlatFS achieves namespace crash-safety guarantees for conventional metadata syscalls and compound directory range operations.

3.2 FlatFS Architecture

FlatFS system architecture is presented in Figure 2. There is no cached namespace in the VFS. The namespace operation is directly performed on the device. There are four types of files in FlatFS: regular file, directory, symbolic link, and hard link. The file metadata is indexed by its full pathname relative to the FlatFS mount point.

In the system call layer, FlatFS provides a compatible hierarchical namespace view. Applications still use hierarchical file paths to access files and directories in FlatFS namespace.

In the virtual file system layer, we design a coordinated path walk (§4.1). The FlatFS namespace also appears in the VFS namespace to preserve a global unified namespace view. The coordinated path walk incorporates two distinct path walk models. It cooperates with the VFS directory tree to perform path walk across distinctive file system namespaces and dispatches requests to the corresponding file system instance.

In the file system layer, index keys are managed by a range-optimized persistent B^+ tree (§4.2). All index keys are sorted in an lexicographical order. B^+ tree is carefully designed with NVM properties [46]. Besides, B^+ tree supports data structure level range operations based on two proposed tree structure primitives: *join* and *split*. It facilitates designing low-cost directory range operations (e.g., *rename*) and simplifies their implementation (§4.3).

In the key storage layer, the idiosyncratic NVM systems pose severe challenges to index key management. Frequent index key updates incur a large number of small random memory writes and cache line flushes, which is especially harmful to system performance [46]. FlatFS adopts a write-optimized compressed key layout to avoid most memory writes and cache line flushes during key inserts and removes (§4.4).

Figure 3: Two Path Walk Models

4 Design and Implementation

4.1 Coordinated File Path Walk

Coordinated file path walk applies two path walk models to resolve a pathname. A path component could be in five different forms: “.” (dot), “..” (dot-dot), normal file, directory, and symbolic link (symlink). Figure 3 illustrates these two path walk models. The component-at-a-time path walk model resolves path component one by one while the full-path-at-a-time path walk processes the whole pathname at a time. This section describes how our path walk model correctly handle different kinds of path components and permission checking as well as coordination between these two models.

Pathname analyzer. The pathname analyzer generates a canonical pathname without any dots and redundant slashes by performing lexical processing on the file path. If FlatFS adopts the Plan 9 lexical file pathname [29], the analyzer resolves a dot-dot component by removing the path component before it. Otherwise, the dot-dot component is handled by the semantic path component finder, which will be described later. After analyzing, FlatFS passes the canonical pathname to the semantic path component finder.

Semantic path component finder. The pathname analyzer can only handle non-semantic path components. The semantic components (i.e., symbolic links and mount points) are identified by the semantic path component finder using a key indexing approach. Specifically, these two kinds of semantic components have associated entries $\langle \text{path}, \text{ino} \rangle$ in the B^+ tree. Besides that, there is another special *finder* entry with the key $\text{path}/\backslash\text{xFE}$ for each of these components in the B^+ tree¹. The *finder* entry value denotes component type. According to B^+ tree lookup policy, if there is no equal entry for the requested key, the first entry whose key is greater than the requested key is returned. For example, if the file path is $/a/./b/\text{link}/c$ where *link* is a symlink, the associated *finder* entry key is $/a/b/\text{link}/\backslash\text{xFE}$. The pathname analyzer output is $/a/b/\text{link}/c$. Because $/a/b/\text{link}/\backslash\text{xFE}$ is the first key that is greater than $/a/b/\text{link}/c$, this *finder* entry is returned during B^+ tree lookup.

Further, there is a remaining problem in finder design: a symlink following a dot-dot component. Suppose a path is $a/\text{symlink}/..$ in which *symlink* points to b/c , and the *symlink* element is removed after pathname analyzing. In

¹The ASCII character $\backslash\text{xFF}$ is reserved for shadow entry, see §4.3

Figure 4: Two-dimensional Prefix Permission Compression

contrast, the component-at-a-time path walk will follow the symlink and generate a resolution result a/b . One solution is using the finder to check whether the current resolved path contains a symlink whenever meeting a dot-dot component during pathname analyzing. This approach degrades path walk performance if there are many dot-dot components in a file path. Another solution is using Plan 9 lexical file pathname [29]. It has better performance but causes compatibility issues. To address this dilemma, FlatFS lets users decide which file path type during file system mount.

If there are no semantic components in a path, FlatFS directly uses the pathname to search the namespace B^r tree to find the associated file inode.

Prefix permission checker. When the user accesses a file, the file system verifies whether the calling process has the execute permission for each directory listed in the file path. We call it prefix permission checking. FlatFS separates the prefix permission checking from the pathname lookup and adopts two-dimensional prefix permission compression to reduce checking performance costs.

First, directories in a file path often have same permission fields [15]: UID, GID, execute permission bit. FlatFS compresses these directory permission fields into a structure called *prefix permission compressor* (PPC for abbreviation), as shown in Figure 4a. The *depth* field denotes how many levels of directories are compressed in this PPC. Second, PPCs of those directories whose index keys are in the same B^r tree leaf node also can be compressed based on the file path (depicted in Figure 4b). The permission fields of the file path prefix are compressed into the path-prefix PPC. The permission fields of the remaining file path are compressed into the path-suffix PPC. File-path-based prefix permission compression is helpful in batching PPC updates.

A directory permission change may cause PPC decompression. Figure 4c illustrates a path-prefix PPC is decompressed into three PPCs caused by a *chmod*. Every new PPC records compressed permission fields of a sub-file path. Moreover, this decompression is propagated to PPC of all sub-directories and associated files under `/usr/src/dir` directory. Fortu-

nately, the file-path-based compression reduces update costs. If keys in a leaf node share a prefix `/usr/src/dir`, only the path-prefix PPC in tree leaf node is updated. Further, as directory permission changing are rare operations reported in a recent research paper [15], the PPC decompression incurs a slight performance impact on realistic applications.

The PPC allows batching permission checking. When performing a prefix permission checking, the task uses its credential to verify the UID and GID in both path-prefix and corresponding path-suffix PPCs. Then, it compares the directory depth of the file path and total execution bits compressed in path-prefix and path-suffix PPCs. If they are equal, file access permission is granted. For a relative file path, FlatFS extracts associated permission bits in path-prefix and path-suffix PPCs according to the path to be checked, and then performs permission checking.

The symlink and dot-dot components require careful consideration to preserve the semantic. If a symlink points to an absolute path, it may cause a namespace switch. FlatFS performs prefix permission checking on file path parts which belong to its namespace. Similarly, when adopting non-lexical file paths, FlatFS also performs prefix permission checking on path components before the dot-dot component. Overall, current POSIX prefix permission checking specification is more beneficial to the traditional path walk model.

Path dispatcher. Path components like dot-dot, symbolic link, and mount point could cause namespace switches during path walk. The path dispatcher performs a namespace switch and sends the pathname to the path walk model. Although the destination namespace may be hierarchical or flat (case I & II in Figure 3), the switch procedure is the same, mainly including mount point switch, pathname cursor adjustment, and other environment setups. In addition, If a symlink points to a relative file path (case III in Figure 3), the path dispatcher generates a new file path by resolving the symbolic link and restarts the whole path walk.

Coordination. A file path walk may involve different path walk models. These different path walk models are coordinated to resolve a pathname correctly. A path walk model can be viewed as a black box. Feeding a pathname input, it generates the resolved pathname output. The key to coordination is ensuring correct path walk model switch. Specifically, the VFS uses a pair $\langle \text{mnt point}, \text{root dir} \rangle$ to specify a mounted file system. We also create one for FlatFS instance, which is used to switch in or out its namespace. Furthermore, we add a pathname cursor for each path walk model to indicate the current resolved pathname position. This cursor feeds a correct pathname input to the path walk model.

4.2 Range-optimized Index Tree

FlatFS uses a persistent range-optimized B^r tree as its indexing data structure. The index keys of B^r tree are full pathname byte strings. Figure 7 shows the B^r tree leaf node layout. The tree node is aligned to 256 bytes, which is the optimal Optane

Figure 5: Tree Join Example: $T_1 \bowtie T_2 = T$

memory access granularity [46]. The keys in the B^r tree nodes are unsorted [12]. Two small pieces of metadata (a bitmap and an offset array) are added into the leaf node. B^r tree adopts a hand-over-hand locking scheme with a top-down locking order. Every tree node owns a readers-writer lock.

Directory range operations in flat namespace are more expensive than the hierarchical namespace tree [47]. B^r tree provides range operations at data structure level to overcome this challenge. The range operations are realized based on two novel tree structure primitives: *join* and *split*. We use symbol \bowtie and \ominus to denote tree join and split primitive, respectively. Also, we define tree node fanout f and total tree items N . The whole tree is locked during range operations.

Tree join. The \bowtie primitive concatenates two smaller trees T_1 and T_2 and generates a larger tree T : $T_1 \bowtie T_2 = T$. The maximum key in T_1 must be smaller than the minimum key in T_2 . Figure 5 illustrates an example of joining T_1 and T_2 . These two tree heights are h_1 and h_2 respectively, where $h_1 > h_2$. The detailed tree join steps are described as follows. First, we walk downside the T_1 from top level to the level $h_1 - h_2$ by always walking the rightmost tree node in each level (Step ①). Then, we concatenate these two trees by merging $node_1$ and $node_2$ (Step ②). The key numbers of these two nodes are m and k . If $m + k \leq f$, we only need to copy all keys and children from $node_2$ to $node_1$. Otherwise, the key number of two nodes is re-balanced as $(m + k)/2$. These associated keys and children are moved from $node_2$ to $node_1$. Finally, a new subtree $tree_2$ is inserted into the parent node $node_0$ (Step ③). The time complexity of tree join \bowtie is $O(|h_1 - h_2|)$.

Tree split. The \ominus primitive splits the tree T into two smaller trees $LTree$ and $RTree$ for split point x : $T \ominus x = \{LTree, RTree\}$. The maximum key of $LTree$ is less than x and the minimum key value of $RTree$ is greater than or equal to x . Figure 6 depicts tree split steps with the split point 9.

At the root node level, we divide all keys in the $node_1$ into two parts. The maximum key of the left part is smaller than 9. The minimum key of the right part is greater than or equal to 9. This key division also partitions the tree into two subtrees L_1 and R_1 . Then, we walk down to the $node_2$ pointed by child C_1 . The key in $node_2$ is in the range of $[5, 20]$. Similarly, keys in $node_2$ also can be divided into two parts. As a result, two subtrees L_2 and R_2 are generated. This operation is repeated until reaching the leaf level. Finally,

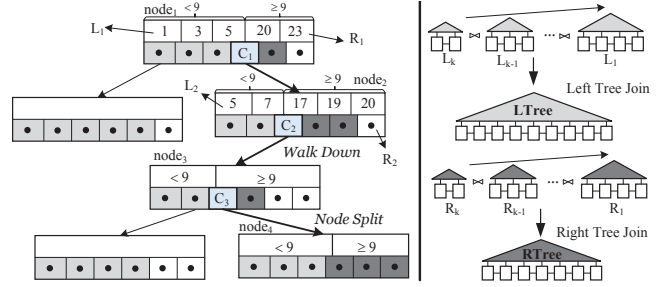

Figure 6: Tree Split Example: $T \ominus 9 = \{LTree, RTree\}$

this tree split generates two small tree sets: $\{L_1, L_2, \dots, L_k\}$ and $\{R_1, R_2, \dots, R_k\}$. Then, we perform tree join operations on all trees in each tree set in an ascending order of tree height. For example, the $LTree$ is generated by joining k subtrees: $L_1 \bowtie L_2 \dots \bowtie L_k$. Finally, the tree T is split into two trees: $LTree$ and $RTree$. The time complexity of \ominus operation is $O(\log_f N + \sum(h_i - h_j)) = O(\log_f N)$.

Range operation. B^r tree provides four range operations: *range query*, *range slice*, *range insert*, *range update*. The range query operation workflow is the same as a textbook B^+ tree. The range slice operation detaches a subtree t from the original tree T with a given key range $[k_l, k_r]$. The detailed range slice steps formulate as follows:

$$T \ominus k_l = \{p, q\} \Rightarrow q \ominus k_r = \{t, r\} \Rightarrow p \bowtie r = T' \quad (1)$$

First, we split the tree T into two parts $\{p, q\}$ for k_l using a \ominus operation. All keys in tree q are greater than k_l . Thus, the tree q is split again with the key k_r . Keys of tree t locate in the range $[k_l, k_r]$. Consequently, the tree t is the range slice result. However, the original tree T structure is destroyed by two split operations. We heal the tree T by using a \bowtie operation to concatenate the p and r . The tree range slice operation is useful in the directory remove and move operation because it can remove a bunch of indexes for targeted files and directories from the B^r tree at a time.

The tree range insert operation inserts a small tree into a large tree at a time. There are two cases for a tree range insert. To insert a tree T_2 into another tree T_1 , if all keys in T_2 are smaller than keys in T_1 , we can directly join these two trees: $T_1 \bowtie T_2 = T'_1$. Otherwise, the tree range insert operation formulates as follows:

$$T_1 \ominus key_{min} = \{T'_1, T_r\} \Rightarrow T'_1 \bowtie T_2 = T''_1 \Rightarrow T''_1 \bowtie T_r = T'''_1 \quad (2)$$

The tree T_1 is split into T'_1 and T_r with the minimum key key_{min} of tree T_2 . The keys in T'_1 , T_2 , and T_r are in ascending order: $key_{T'_1} < key_{T_2} < key_{T_r}$. This range insert operation is achieved by performing two join operations on three trees.

The tree range update modifies the index keys of a specific range. A naive solution to range update is walking the tree and updating all index keys in tree nodes. Our B^r tree uses the WoC key design to reduce the key update costs. The WoC key fetches the common part of all index keys as a key prefix. Therefore, the range update operation only modifies the key prefix without updating these keys one by one.

Leaf node caching. We design a leaf node cache to reduce tree walk performance costs. Every CPU owns a volatile in-DRAM node cache structured as a LRU list. The cache entry stores the leaf node memory address instead of the real leaf node. Hence, no data synchronization is required among multiple CPU caches. The B' tree lookup consists of a fast path and a slow path. The fast path traverses the LRU list, locks and accesses these real leaf nodes, and searches for the item with the requested key. If there is a hit, the slow path that walks the whole tree can be avoided. The leaf node cache is effective as namespace operations in the real world often exhibit good locality. For example, creating files in a directory needs to search the same directory file inode multiple times.

Every leaf node has a reference counter for safe memory reclamation. Creating a node initializes the counter as one, and the cache insertion increases the counter. Because the cache is volatile, no crash safety is needed for counters. They will be reset as one during remount. A cache entry may refer to a removed tree node. The removed node with a non-zero counter is kept in a persistent list for lazy reclamation. Accessing the removed node is safe since it contains no valid keys due to the empty bitmap. This node will be recycled when the associated cache entry is evicted.

4.3 Directory Range System Call

Besides *rename*, FlatFS designs three new system calls for directory range operations.

Directory read. FlatFS offers a *getdents_recur* system call. This system call lists all files and subdirectories in a directory recursively (similar to *ls -R*). To support recursive range query for a directory, FlatFS introduces two shadow entries for each directory. Their filenames are the first and last ASCII character. Keys of all entries in the directory are delimited by these two shadow entry keys. To perform a recursive directory reading, FlatFS uses the small shadow entry key to lookup the tree to find the leaf node. Then, it repeats this with the other large shadow entry key and fetches a range of keys at a time. For non-recursive directory reading, FlatFS uses a directory skip approach. When FlatFS meets the first shadow entry of a subdirectory during directory scanning, it skips entries in the subdirectory by performing a tree lookup with the other shadow entry key.

Directory remove. FlatFS introduces a new system call *rmdir_recur*, which is used to remove all files and subdirectories in a directory at a time. In the data structure layer, we use a range slice to obtain the subtree that contains entries to be removed from the B' tree. Then, we perform a range query to this subtree, find inodes of these files and directories, remove files and directories at the file system layer. To further reduce the *rmdir_recur* latency, we also delay freeing the sliced subtree structure.

Directory copy. FlatFS provides a new system call *cpdir_recur(src, dst)*, which copies a directory recursively to another directory. First, the subtree of *src* directory is sliced

and duplicated. The index key updates of the duplicated tree are batched. Then, both sliced and duplicated subtrees are inserted into the B' tree. Then, new metadata are created for copied files and directories. We follow the default semantic of *cp -r* for hard links, i.e., the linking becomes invalid. A new inode is allocated for the copied hard link and its file content is the same as the original linked file. Besides, FlatFS also corrects the inode number of dot and dot-dot of every directory, making them point to the newly created directory and its parent directory. Another performance optimization adopted by *cpdir_recur* is file data copy-on-write mechanism. We only duplicate the file mapping of every copied file. The last level pointers in the file mapping are set as copy-on-write.

Directory move. The directory rename mainly involves data structure level operation. Similar to directory remove, the subtree of the *src* directory is sliced. Then, all index keys of the subtree are updated with the *dst* directory. Depicted in Figure 7, every tree node contains an index key prefix. A key update traverses the B' tree and iterates over every node. If the *src* directory pathname is a substring of the key prefix in this node, this key update just modifies the key prefix with the *dst* directory pathname. Finally, the updated subtree is inserted into the B' tree.

4.4 Write-optimized Compressed Key

FlatFS uses key compression to reduce storage consumption and key batch update costs. Every variable-size index key is divided into a prefix and a suffix. All index keys in the same tree node share a prefix. However, key compression incurs performance overheads due to prefix and suffix adjustments. For example, inserting a key would shrink the prefix and expand all suffixes, leading to many small data writes, which causes expensive cache line flushes and write amplification.

Basic idea. We propose WoC key to address this challenge. WoC key prefetches a number of characters during suffix expansion. These data are cached in the suffix to avoid future data movements. Moreover, we also record the prefix size and the total size of each key. Suppose another key insert event causes all suffixes to expand and suffix size increasing. Fortunately, we only need to update the prefix size to represent all suffix data and size changes.

Furthermore, removing a key may cause all suffixes to shrink and the prefix to expand. There are no data movements for suffix shrinking. We append data to the prefix and increase the prefix size. There is no data prefetch optimization for the prefix because a tree node only has one prefix, and its adjustment cost is low. In contrast, every node entry owns a suffix. Suffix changes lead to high memory write costs.

Detailed Design. Figure 7 shows the key suffix is partitioned into inuse area and cache area. The *key suffix addr* stores suffix memory addresses. The inode number is stored along with the suffix. The *woc-length array* contains a set of eight-bytes *woc-length* structures. Every index key owns a suffix and a *woc-length* structure. The total key size *key_total_sz*

Figure 7: B^+ Tree Leaf Node and Index Key Layout

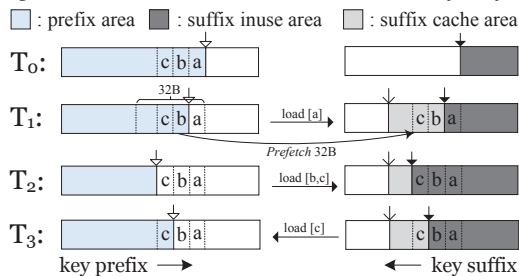

Figure 8: Illustrative Examples of Suffix Prefetch and Caching and the suffix size key_suff_sz are stored in the woc_length . The key_suff_sz is the sum of suffix inuse and cache area size. The inuse area size is $key_total_sz - prefix_sz$. If the cache area size is smaller than the data to be appended, it indicates the suffix cache is insufficient and requires another prefetch.

Figure 8 illustrates three examples of how to reduce data movements with WoC key design. At time T_1 , one-byte data a is moved to the suffix area. Instead of moving one character, we prefetch 32-bytes of data from the prefix memory area to the suffix memory area. Then we modify $prefix_sz$ and key_suff_sz and persist these two fields. 32 bytes is the optimal data prefetch granularity according to evaluation results. Prefetching 64-bytes data may introduce two cache line movements if the first byte of prefetched data is not cache-line aligned. On the other side, a smaller prefetch granularity introduces more frequent data movements.

The prefetched data are stored in the cache area to avoid future data movements. For instance, at time T_2 , two bytes of data $[b, c]$ are moved to the suffix area. Fortunately, these two-bytes data are already stored in the suffix cache area. We only need to update the $prefix_sz$ field to indicate this key suffix expansion. When the key suffix shrinks at time T_3 , the associated data c is appended to the key prefix. There are also no data movements for this suffix shrinking event.

The key batch update introduces two issues to WoC key design: (1) if a key batch update modifies the key prefix, the key_total_sz fields of all key suffixes should be updated; (2) a key batch update may cause cached data in the suffix to become stale due to key prefix change. To solve the first problem, we introduce a $\Delta prefix_size$ field, which denotes

the key size changes to all index keys in a tree node caused by a batch update. Instead of updating all key_total_sz fields, the key batch update modifies the $\Delta prefix_size$. The key suffix inuse area size is $key_total_sz - prefix_sz + \Delta prefix_size$.

The second problem is addressed by introducing a dirty suffix bitmap. The bitmap records those key suffixes whose cached data become stale in the index key batch update. We query the dirty bitmap before adjust the key suffix. If the associated suffix cache area is dirty, we clean the suffix cache area by resetting key_suff_sz as the suffix inuse area size.

4.5 Namespace Crash Consistency

Existing metadata system calls except for *rename* only introduce tree point operation. The general workflow of these system calls consists of three steps: (1) pathname lookup; (2) inode manipulation; (3) tree point operation. Achieving crash consistency for these system calls is similar. We take *creat* system call as an example to describe the approach.

First, the newly allocated inode is logged at the file system layer. Then, FlatFS inserts a new entry into B^+ tree. This entry insert may be a simple leaf node insert or requires a node split. In the worst case, a leaf node insert causes a key prefix adjustment, a new key suffix write, a cascade of updates to other key suffixes, and a valid bitmap update. Thanks to the WoC key design, we only needs to log 18-bytes data (2-bytes prefix size, 8-bytes prefix address, and 8-bytes valid bitmap). Logging key prefix size and address ensures data consistency for both key prefix and suffix. To be specific, all old suffix sizes can be restored with logged old prefix size. Then we reset key_suff_sz as key suffix inuse area size. The key prefix is also restored using logged old prefix address. In addition, if there is a node split for this entry insert, the valid bitmaps of the split node and parent node are also logged.

Ensuring metadata consistency is challenging for directory range operations as they introduce complicated tree structure manipulation. We first explain how to ensure crash-safety for B^+ tree range operations. Depicted in Figure 5, a tree join involves three nodes: two merged nodes and a parent node. The valid bitmaps of these nodes are logged. Ensuring crash consistency for tree splits is more difficult. Supposing the tree T height is h , the \ominus operation splits h nodes at each tree layer with split point x . The valid bitmap of h nodes is logged. Next, two new trees L and R are generated by joining these split trees in two sets separately. It seems difficult to recover the tree state if a crash occurs during tree joins. A useful property between \bowtie and \ominus simplifies the crash-consistency implementation, i.e., \ominus is the reverse operation of \bowtie . The original tree T can be recovered by joining L and R : $L \bowtie R = T$. Thus, root node memory addresses of joined trees (i.e., $\{L_1, \dots, L_k\}$ and $\{R_1, \dots, R_k\}$) are logged. During recovery, we replay tree join operations with logged root node addresses and re-generate the namespace tree T with L and R .

The tree *range insert* and *range slice* are implemented based on tree join and split. We already guarantee crash-

Figure 9: Path Walk Efficiency

safety for tree \bowtie and \ominus . Crash consistency of these two tree operations is achieved based on an important insight. Even the original namespace tree is temporarily decomposed into many pieces due to split/join, however, it still can be rebuilt by joining these subtrees during recovery. Finally, FlatFS also logs these affected inodes for directory range operations.

5 Evaluation

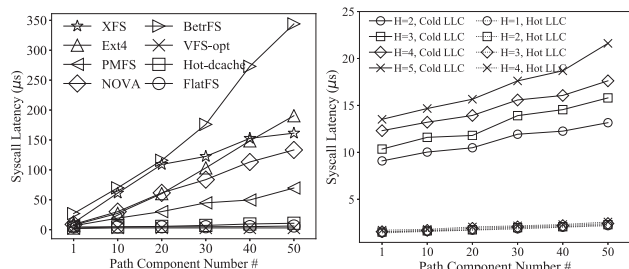

Our testbed machine has two Intel Xeon Gold 5220R processors. Each processor has 24 physical cores running at 2.2 GHz. Every physical core has a private 32 KB L1 cache and a 1 MB L2 cache. All cores that resided on the same socket also share a 35.75 MiB last level cache. The hyper-threading is disabled. Each processor has two integrated memory controllers. The machine has 192 GB (12×16 GB) DRAM, 1.5 TB (12×128GB) Intel Optane DC persistent memory, and a 512 GB Solid State Driver.

We implement FlatFS in Linux kernel 4.15 based on PMFS file system [31]. FlatFS reuses PMFS data path and journal mechanism. We compare FlatFS with four NVM file systems (NOVA [44], PMFS [31], Ext4 [5] and XFS [37]), a full-path-indexing file system BetrFS [47], a VFS dcache optimized system (VFS-opt) [40]. BetrFS and VFS-opt work on Linux 3.11.10 and 3.14, respectively. These old kernels do not support Intel Optane memory. We use Linux *brd* module to create a RAM disk for BetrFS and VFS-opt. The RAM disk uses the fast DRAM to emulate block devices. The device performance is better than the Optane memory. We also mount an Ext4 file system on the RAM disk for VFS-opt.

5.1 Microbenchmark Performance

Path walk efficiency. We evaluate the path walk performance with different kinds of path components. We *stat* a file whose path comprises nine components in the Linux kernel 4.4 source code directory. When dcache is cold, file systems fetch data from the device, which causes long latency. This problem is especially serious for BetrFS. BetrFS adopts a stacked system architecture. A dentry missing event is handled by multiple software layers. Its path walk latency is 11.93× higher than FlatFS. The sequential file access results in a hot dcache, which greatly reduces path walk latency. Fortunately, FlatFS also achieves low latency thanks to its node cache design. The VFS-opt delivers the lowest latency (3µs) for its hash-based full-path-indexing optimization.

VFS and FlatFS handle dot components lexically. Thus, the

(a) Path Walk Scalability

(b) Path Walk Sensitivity

Figure 10: Path Walk Scalability and Sensitivity

Table 2: Path Sensitivity to Sequential and Random Access. H: B^r Tree Height; L: File Path Length; N: File Number

| Setting | H=3, N=10 ⁴ , L=20 | | H=4, N=10 ⁵ , L=20 | | H=5, N=10 ⁶ , L=20 | |
|---------|-------------------------------|--------|-------------------------------|--------|-------------------------------|--------|
| System | VFS | FlatFS | VFS | FlatFS | VFS | FlatFS |
| Seq. | 2.05µs | 1.63µs | 2.04µs | 1.63µs | 2.05µs | 1.63µs |
| Rnd. | 2.11µs | 2.19µs | 2.24µs | 2.54µs | 2.26µs | 3.66µs |

path walk latencies are similar to the cold dcache case. FlatFS performs semantic path component checking for dot-dot and symlink components, which incurs an extra namespace tree query. Even so, FlatFS performs 1.87-28.52× better than others for its non-caching namespace design. Finally, we mount an Ext4 file system under each tested file system. The mount operation causes a hot dcache for path walk. The performance results are similar to the hot dcache case. Overall, for a nine-component path, FlatFS outperforms other file systems significantly for the cold dcache and delivers similar latencies for the hot dcache.

Path walk scalability. We vary path component number from 1 to 50 to evaluate path walk scalability using *stat* syscall. As shown in Figure 10a, when the file path becomes lengthy, the execution latencies of five file systems (i.e., BetrFS, XFS, Ext4, PMFS, NOVA) also increase significantly. The FlatFS path walk latency (5.1µs) is stable against different path lengths. The VFS-opt system achieves a low constant path walk latency (3µs). We also measure the path walk scalability of hot dcache. When the path component is less than 10, its latency is close to ours. However, its latency increases 5× (10.8µs) varying from 1- to 50- component.

Path walk sensitivity. We evaluate FlatFS path walk sensitivity by changing four variables: B^r tree height, Last-Level-Cache (LLC), path component number, and access pattern. We create four file sets of different sizes (10³, 10⁴, 10⁵, 10⁶) with tree height H ranging from 2 to 5. We vary the path length and measure the syscall latency. We make three observations from Figure 10b. First, hot LLC significantly boosts FlatFS path walk performance. Second, path walk performance is sensitive to tree height, especially for cold LLC. Resolving a 50-component path in a 5-level B^r tree takes 21.61µs, which is 1.64× longer than 1-level B^r tree. Third, path length has a slight impact on FlatFS path walk performance. A 50-component path walk is 1.5× longer than 1-component. In contrast, other file systems deliver 9.8×-16.3× latency increment in Figure 10a.

Table 3: Directory Range Operation Latency (s)

| | Ext4 | XFS | NOVA | PMFS | BetrFS | VFS-opt | FlatFS |
|---------|-------|-------|-------|-------|--------|---------|--------|
| readdir | 0.152 | 0.349 | 0.208 | 0.097 | 0.388 | 0.157 | 0.031 |
| rmdir | 0.61 | 1.262 | 1.131 | 0.548 | 3.680 | 0.736 | 0.190 |
| cpdir | 2.398 | 2.907 | 2.334 | 1.949 | 4.652 | 1.829 | 0.450 |
| mmdir | 0.004 | 0.004 | 0.004 | 0.004 | 0.019 | 0.004 | 0.007 |

Table 2 shows path walk latency of sequential and random file access. The LLC and VFS dcache is warmed before experiments. FlatFS outperforms VFS for sequential access in three settings. The reason is batched operations in FlatFS path walk. To confirm it, we use the perf tool to collect instruction numbers during syscall execution in setting S_3 . The profiling results report that VFS executes 1.43× more instructions than FlatFS. Random access has a larger impact on FlatFS than VFS. VFS gains much more benefits from its cached dentries of the prefix path. Random access causes 3.24× more cache misses for FlatFS than VFS. As the file size decreases, FlatFS also achieves better performance for higher LLC hit ratio. Finally, sequential access outperforms random access due to higher node cache hit ratio.

Directory range operation. Table 3 shows four common directory range operation performance. FlatFS uses four directory range system calls. For other file systems, we use `ls -R`, `rm -r`, `cp -r`, and `rename` instead. All directory range operations manipulate a Linux kernel 4.4 source code tree.

Reading a directory recursively is well-optimized in FlatFS. FlatFS reduces directory read latency by up to 12.52× compared to others. These file systems except BetrFS scatter the dentries in data blocks across the storage device, which greatly hurts the data locality. For directory removing, FlatFS obtains performance gains from 2.88× to 19.37× relative to other file systems. Since namespace traversal is fast in FlatFS, it benefits directory remove as FlatFS only needs to perform a simple scan to obtain the entries for de-allocation. Other file systems require expensive tree traversal to retrieve target inodes. Also, FlatFS delays freeing the directory subtree to further reduce the latency.

FlatFS outperforms other file systems by 4.06×-10.34× for directory copy. Because the directory copy is data I/O dominated. The file data copy-on-write optimization in FlatFS effectively avoid such performance costs. BetrFS is well-optimized for HDDs. For ultra-fast NVMs, its stacked architecture is suboptimal. We find interactions between BetrFS and the underlying storage device involve many software layers, which causes high software latencies due to both additional and duplicated works. Directory move is the only range operation provided by conventional file systems. Directory move is cheap for the hierarchical namespace structure, which only takes 4μs for moving a Linux directory tree. FlatFS also achieves a low rename latency 7μs using tree-level range operation and batching key update.

5.2 Macrobenchmark Performance

Filebench. We choose two application-level workloads: fileserver and varmail from Filebench [38]. We create a file set

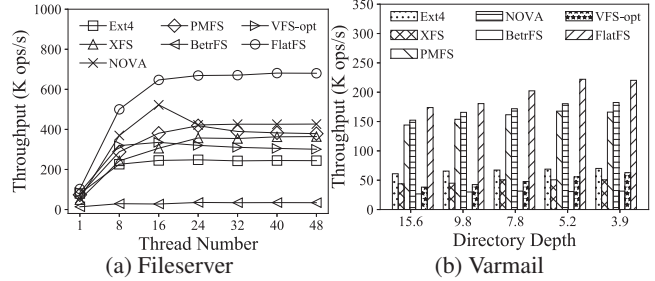

Figure 11: Performance of Filebench Benchmark

with 100 thousand 4KB files for the fileserver. We stress the namespace performance by setting the average directory width as two. Figure 11a shows the fileserver throughput varying thread number from 1 to 48. FlatFS achieves a 1.79 performance speedup over PMFS. FlatFS and PMFS share the same file data path but differ in metadata management. When thread number increases, PMFS suffers from poor scalability due to its centralized inode table design. NOVA and FlatFS address this issue with per-CPU inode table design. NOVA performs worse than FlatFS for its low namespace insert/remove performance and fault tolerance costs [45]. NOVA uses a Radix tree to manage entries in the directory. A `create/unlink` inserts/removes the associated entry in the parent directory. Because a directory only has two files, file creation/removal incurs high tree management costs.

The centralized journal in Ext4 also causes severe scalability issues [19,35]. VFS-opt requires Ext4 to create files, which accounts for its low scalability. VFS-opt achieves 23% higher throughput than Ext4 for its dcache optimization. Finally, BetrFS exhibits the lowest performance. Since the cache is hot during execution, we explain it as NVM-unaware B^e tree design. B^e tree adopts big internal (4MB) and leaf nodes (4-11 MB). Moreover, it uses an order maintenance tree (OMT) to organize entries inside the leaf node. The entry insert or remove is expensive because it introduces many entry movements and OMT adjustment costs during file create and remove. In contrast, FlatFS reduces key management costs during tree insert/remove with its write-optimized key design.

In varmail experiment, we create a file set that contains 50 thousand 64-byte files to simulate a large set of small e-mails in the mailbox. We vary the `meandirwidth` parameter from 2 to 16. It affects the directory depth of the tested file set. When the directory depth increases, the path walk time increases. Therefore, the throughput of all file systems decreases. FlatFS obtains 14.10%-3.97× higher throughputs than other file systems due to its fast path walk design. Moreover, varmail workload frequently creates and deletes files. Besides fast path walk, FlatFS also gains performance benefits from its high namespace insert/remove performance.

FxMark. We pick MWCM and MWUM benchmarks from FxMark [25] to measure the file system multicore scalability. Figure 12a and Figure 12b shows experimental results. We draw three conclusions from these experiments. First, FlatFS performs much better than other file systems in file creation

Figure 12: Scalability of FxMark Benchmark

and removal, which achieves a maximum $2\times$ performance speedup. Other file systems exhibit low namespace insert/remove performance due to inefficient dentry index structure design. For instance, PMFS uses a linear array to organize entries in a directory [31]. When there are a large number of files, searching an entry in the linear array takes long time. We even fail to run these two benchmarks on PMFS and BetrFS due to their extremely low dentry search performance.

Second, the inode lock is the major scalability bottleneck for file creation and removal. All in-kernel file systems including FlatFS adopt the same inode locking scheme. Thus, their performance trends with different thread numbers are similar. However, FlatFS still outperforms others for its higher namespace performance. Third, NUMA impacts greatly affect file system scalability. Both Figure 12a and Figure 12b show that all file systems experience a degradation when there exists remote memory node access beyond 24-threads.

5.3 Factor Analysis of Each Optimization

We analyze the performance benefits of three optimization techniques in FlatFS.

Figure 13: Performance Benefit of Node Cache and WoC Key

Node caching optimization. The node cache design avoids tree traversal for entries in the same tree node. It is especially useful for sequential file access. We create four large directories containing 10^4 , 10^5 , 10^6 , 10^7 files, respectively. The corresponding B^+ tree height ranges from three to six. We create a microbenchmark to access all files in the directory. Figure 13a shows FlatFS achieves 2.01%-11.07% performance improvements with node caching optimization. In addition, when tree height increases, FlatFS obtains more benefits from tree node caching.

Rename optimization. The rename operation is cheap and fast in directory tree-based namespace. It takes 0.004s to move a Linux-4.4 source code repository. We measure two

rename implementations in FlatFS. The slow *rename* implementation removes all associated entries in the flat namespace, updates pathname keys, and then inserts all entries. Its latency is ten times slower than conventional file systems. Fortunately, FlatFS improves *rename* performance with tree range operation. Its optimized *rename* takes 0.007s.

WoC key design. We use a microbenchmark to measure the performance benefits of WoC key design. The microbenchmark creates a large number of files in a directory. File creation causes index key prefix and suffix adjustments, which incurs high data persistence costs. Figure 13b demonstrates that FlatFS+WoC delivers average 15.94% lower latency than FlatFS without WoC key optimization. We also use IPMWatch tool [9] to collect the number of writes received by the memory controller. Figure 13b shows WoC key design achieves a nearly $2.64\times$ write reduction.

5.4 Version Control System: Git

We demonstrate FlatFS performance benefits with git application. We create a large deep directory tree containing ten Apache Hadoop 2.10.1 source code repositories [3]. The average directory depth of all files is 17.71. We use two frequently used git commands `git status` and `git commit` to evaluate file system directory reading and path walk performance. In the original `git status` implementation, it traverses the directory tree of the target repository recursively, reads every directory entry, validates its state, and puts it into the associated list according to its state (e.g., *untracked*). Figure 14a shows that FlatFS outperforms others by up to $2.21\times$.

Besides, we also modify the `git status` implementation using the `getdents_recur` syscall in Section 4.3 (denoted as `Git-opt+FlatFS` in Figure 14a). The `getdents_recur` system call performs a range query to the target directory and sub-directories and returns all entries at a time. It greatly improves `git status` performance by eliminating expensive hierarchy tree traversal. The optimized `git status` only takes 0.6s, which reduces the latency by $4.12\times$ compared to the unmodified `git status` command.

The `git commit` first uses `lstat` to check the file existence, then it opens every file and reads its content using a `mmap` system call. The massive number of `lstat` and `open` syscall in `git commit` greatly stresses the path walk efficiency. The experimental results show that FlatFS reduces the `git commit` latency by 13.79%-37.50% compared to others.

Figure 14: Git and Psearchy Evaluation Results

5.5 File Indexer: Psearchy

Psearchy is a parallel version of searchy [11]. The Psearchy creates multiple worker threads. Each thread processes a number of files. Specifically, the thread opens every file, reads file content, records word positions in a local hash table, sorts word positions, and persists results in a Berkeley DB file. We set the local hash table size 16 MB. We also create a dataset using the taxonomy of known animals from the Catalogue of Life website [4]. The dataset directory hierarchy is generated according to the hierarchy of biological classification. It contains 276,616 files and directories. Because the file size is small, the psearchy performance is largely dependent on file open performance. Figure 14b shows that applications throughput increases as the thread number increases. Among them, FlatFS always achieves the highest throughputs. However, scalability issues caused by the glibc *qsort* function and VFS inode hash table lock prevent throughput improvements as thread number increases.

Table 4: Total and *stat* Syscall Execution Time of Hive

| | Ext4 | XFS | NOVA | PMFS | BetrFS | VFS-opt | FlatFS |
|--------------|-------|-------|-------|-------|--------|---------|--------|
| Total | 8.44s | 8.71s | 8.55s | 8.50s | 8.39s | 8.34s | 8.28s |
| <i>Stat</i> | 1.46s | 1.40s | 1.52s | 1.34s | - | - | 1.18s |
| μ s/Call | 3.07 | 2.94 | 3.20 | 2.81 | - | - | 2.50 |
| Gain | 18.4% | 15.1% | 21.8% | 11.0% | - | - | |

5.6 Data Warehousing System: Hive

Apache Hive is a data warehousing system that uses database table partition to improve data query performance [39]. We use TPC-H benchmark [8] to create a database table for evaluation. Then we use table partition technique to generate a dataset containing 74,090 files and directories. We create a Hive SQL benchmark to perform queries to all files. The major performance bottleneck of Hive is the Java virtual machine. Therefore, Table 4 shows FlatFS slightly outperforms other file systems in total execution time.

During Hive execution, We find that *stat* is the most frequently invoked metadata syscall. To measure the performance benefits of our namespace design, we uses the *strace* tool [7] to collect the *stat* syscall execution time. We fail to profile BetrFS and VFS-opt due to unknown bugs. Table 4 reports that FlatFS achieves 16.58% better performance than others in *stat* syscall for its optimized file path walk.

6 Related Works

File Metadata Indexing Optimization. TableFS [32] and BetrFS [18] share similar idea that utilize existing key-value stores (LevelDB and TokuDB) to improve metadata indexing performance. TableFS [32] aggregates file metadata in a LevelDB table indexed by a combination of parent directory inode number and filename string. BetrFS utilizes the TokuDB to optimize both metadata and data block indexing performance with their full-path indexing schema [18]. These two file systems achieve good performance running on hard disks. However, they introduce new software layers into the

existing storage stack. Our experimental results show that such stacked system architecture is inefficient for file systems built for fast NVMS. FlatFS exhibits a non-caching system architecture to avoid data copy costs for ultra-fast NVMS.

File Path Walk Optimization. ByVFS [41] bypasses the VFS layer during path component resolution and directly fetches dentries from the device. Tsai et al. [40] propose two techniques to improve file path walk performance in the VFS layer. First, they reduce the pathname lookup latency using full-path indexing via an in-memory hash table. Second, they reduce the dcache hit latency by caching the permission results of file paths. DLFS [21] re-organizes the on-disk metadata and proposes a hashing-based metadata indexing solution to improve pathname lookup performance. Directory range operations (e.g., *rename*) are expensive in their system. FlatFS incorporates a full-path-at-a-time path walk model to accelerate pathname lookup performance.

Namespace Structure Optimization. ReconFS [22] decouples the file system namespace as a volatile and a persistent directory tree. It improves system performance and device endurance by reducing metadata writes to flash memory. Partition is an efficient solution to improve namespace scalability. IndexFS [33] proposes a scalable directory service based on GIGA+ [27] to dynamically partition a large directory tree across multiple nodes in the distributed environment. SpanFS [19] is a scalable local file system that distributes the global namespace into multiple disjoint domains to avoid contention caused by centralized namespace management. FlatFS exploits the flat namespace structure to optimize the namespace lookup and reading operation performance.

7 Conclusion

This paper demonstrates a novel NVM file system FlatFS. FlatFS exploits flat namespace architecture to improve metadata operation performance by proposing three techniques: a coordinated path walk, a range-optimized B^+ tree, and a write-optimized index key layout. Extensive experiments demonstrate the performance benefits of FlatFS to metadata-intensive benchmarks and applications. FlatFS is open source at <https://github.com/miaogecm/FlatFS.git>.

Artifact Appendix

A.1 Abstract

We provide FlatFS artifact description in this section. FlatFS is a metadata-optimized NVM file system that features a flat namespace. This section describes (1) how to build FlatFS on NVM systems §A.2; (2) how to reproduce the main experimental results of our paper §A.3.

A.2 How to Build FlatFS

This section describes software requirements for FlatFS and how to build FlatFS.

- **OS version:** Ubuntu 18.04 or Ubuntu 14.04.6
- **Kernel version:** Linux 4.15.0

1. Download FlatFS

```
$ git clone https://github.com/miaogecm/FlatFS.git
```

This repository contains FlatFS source code which locates in `linux-4.15/fs/flatfs` and a modified virtual file system that supports coordinated path walk.

2. Compile and Install FlatFS

```
$ make localmodconfig
$ make menuconfig
```

Modify the Linux kernel configuration file, and make sure these two configurations are enabled:

```
File systems/DAX support
File systems/FlatFS
```

and disable these four configurations:

```
Security options/AppArmor support
Security options/Yama support
Security options/TOMOYO Linux support
Security options/Security hooks for pathname based
    access control
```

Compile the kernel

```
$ make -j
```

Install the new kernel:

```
$ make install
$ make modules_install
$ update-grub
```

Reboot the system:

```
$ reboot
```

3. Mount FlatFS

FlatFS can be mounted on a real or an emulated NVM device. Create a mount directory and mount FlatFS:

```
$ mkdir /mnt/flatfs
$ mount -t flatfs -o init /dev/pmem0 /mnt/flatfs
```

4. Umount FlatFS

```
$ umount /mnt/flatfs
```

A.3 Experiment Reproducibility

We provide a number of helpful scripts to reproduce the main experimental results automatically. Specifically, readers could reproduce Figure 9, Figure 10a, Figure 10b, Figure 11a, Figure 11b, Figure 14a, Figure 14b, Table 2, Table 3, and Table 4.

Reproducing an experiment takes three steps except for the Hive experiment.

Step 1. Clean old data:

```
$ ./clean
```

If you are reproducing Table 4, generate data for the experiment first:

```
$ export TBL_PATH=~/.hive/table
$ ./mktable
```

Step 2. Collect data for each tested file system, where FS=ext4, xfs, pmfs, nova, flatfs, betrfs, vfs_opt. The generated data is saved in a `.data` file in the current directory.

```
$ ./run $FS
```

Step 3. Draw the figure with collected data:

```
$ ./plot.py
```

More details can be found in `evaluation/README.md` in the repository.

StRAID: Stripe-threaded Architecture for Parity-based RAIDs with Ultra-fast SSDs

Abstract

Popular software storage architecture Linux Multiple-Disk (MD) for parity-based RAID (e.g., RAID5 and RAID6) assigns one or more centralized worker threads to efficiently process all user requests based on multi-stage asynchronous control and global data structures, successfully exploiting characteristics of slow devices, e.g., Hard Disk Drives (HDDs). However, we observe that, with high-performance NVMe-based Solid State Drives (SSDs), even the recently added multi-worker processing mode in MD achieves only limited performance gain because of the severe lock contentions under intensive write workloads.

In this paper, we propose a novel stripe-threaded RAID architecture, StRAID, assigning a dedicated worker thread for each stripe-write (one-for-one model) to sufficiently exploit high parallelism inherent among RAID stripes, multi-core processors, and SSDs. For the notoriously performance-punishing partial-stripe writes, StRAID presents a two-phase stripe write mechanism to opportunistically aggregate stripe-associated writes to minimize write I/Os; and designs a parity cache to reduce write-induced read I/Os on parity disks. We evaluate a StRAID prototype with a variety of benchmarks and real-world traces. StRAID is demonstrated to consistently outperform MD by up to 5.8 times in write throughput without affecting the read performance.

1 Introduction

The advent of ultra-fast storage devices such as NVMe-based Solid-State Drives (SSDs) and Non-volatile Memory (NVM) with GB/s-level I/O bandwidth has dramatically narrowed the performance gap between memory and storage. Redundant Array of Inexpensive Disks (RAID) [56] can combine multiple such high-performance storage devices to further promote the overall storage performance, reliability, and capacity simultaneously. Many empirical studies [11, 19, 35] including distributed datacenter storage systems [49, 70] and enterprise storage systems [48] report that SSD drivers exhibit

reliability problems in that more than 20% of SSDs develop uncorrectable errors in a four-year period [58]. Therefore, parity-based RAIDs composed of ultra-fast SSDs have become attractive storage systems for modern data-intensive applications in supercomputing [55], big data analytics [27, 64], machine learning [8], enterprise storage [48], and cloud services [1, 32, 38, 46, 61].

HDD-based RAIDs have been extensively studied since 1988 [56]. In the literature, recent studies focus on SSD-based RAID and All-Flash-Array (AFA), with efforts to reduce SSD write-penalty by mitigating parity update [9, 16, 67], reduce garbage-collection induced performance jitter [23, 33, 42], and optimize AFA using declustering RAID approach to balance load within devices and reduce tail-latency [30, 75]. Existing RAID I/O handling techniques generally adopt a centralized stripe-processing architecture following a classic principle that trades more fast-CPU-cycles (e.g., scheduling algorithms) for fewer slow-I/Os. Nonetheless, the question of whether such RAID architecture can fully exploit the power of emerging fast storage remains unanswered.

We experimentally measure the actual performance of Multiple-Disk (MD) [45], the most popular and mature software RAID integrated into the Linux kernel for over two decades. We conduct MD running on 6 NVMe-based SSDs with 64 user threads (i.e., issuing block requests) and 64 workers threads (i.e., handling RAID stripe-writes), with the experiment environment summarized in Tables 1 and 2. The results are shown in Figure 1 (detailed in Section 3.1). With RAID0 (non-parity RAID-level), MD obtains an expected performance that approaches the aggregate raw I/O capacity of the underlying SSDs, i.e., 20GB/s and 14GB/s for read and write throughputs respectively. However, MD falls far short of the expectation in write performance in RAID5 and RAID6 (parity-based RAID-levels). Specifically, the write throughput of RAID5 is below 2.2GB/s under partial-stripe writes and below 5.2GB/s under full-stripe writes, which are only about 1/7 and 1/3 of that of RAID0, respectively. Although parity-RAIDs introduce extra parity-compute overheads, our measured XORing rate on a CPU core can reach

*Corresponding author. Email: caoqiang@hust.edu.cn

up to 29GB/s [29], which is clearly not the bottleneck.

Through profiling (detailed in Section 3.2), we experimentally uncover that the write inefficiency of parity-based RAID comes from a centralized stripe-handling architecture in the legacy MD. Specifically, a worker thread using shared data structures (e.g., stripe-list) handles write requests by efficiently collaborating with user threads, XORing threads, and device I/O threads. For HDDs and slow SSDs, this one(worker thread)-for-all(stripe) architecture utilizes fast CPU sufficiently by postponing stripe-writes to absorb more requests for reducing actual I/Os. However, a single worker thread is upper-bounded in its processing capability that fails to keep up with the fast storage. The latest MD introduces a multi-worker mechanism, referred to as the N-for-all processing model, but achieves a limited performance gain due to severe lock contention on the centralized data structures.

In this paper, we propose a novel stripe-threaded architecture, called StRAID, for parity-based RAIDs built on ultra-fast storage devices such as NVMe-based SSDs. To address the architectural drawback of the existing software RAID (MD), StRAID employs a one(worker)-for-one(stripe) model, thus significantly reducing the number of stripe-states and their lock-based checks. Furthermore, StRAID adopts a fine-grained stripe-level lock, substantially mitigating contentions on shared data structures. To tame the notoriously performance-degrading partial-stripe writes, StRAID further designs a two-phase stripe submission mechanism that opportunistically aggregates subsequent incoming writes belonging to the same stripe within a limited time window. Meanwhile, StRAID proposes a parity-block cache to speed up frequent write-induced parity reads. Fundamentally, StRAID effectively exploits stripe-based data parallelism while mitigating intra-stripe conflicts between the dedicated stripe worker thread and other threads. StRAID leverages the power of multicore CPUs that offers sufficient inexpensive-threads to fully unleash the superior IOPS provided by fast SSDs.

The main contributions of this paper are as follows.

- We experimentally observe a serious write inefficiency problem in the current MD when parity-based RAID is running on ultra-fast storage. We further reveal that the root cause is the centralized one-for-all stripe-handling architecture.
- We propose a novel parity-RAID processing architecture, StRAID, guided by a stripe-threaded one-for-one model to unleash the full performance potentials of modern hardware. We also present two key techniques, opportunistic stripe-aggregation and parity-block cache, to improve the performance of partial-stripe writes.
- We prototype and evaluate StRAID with a variety of benchmarks and real-world workloads. StRAID consistently outperforms MD by up to 5.8 times in write throughput without affecting the read performance while reducing CPU utilization.

The rest of the paper is organized as follows. Section 2 presents the background for RAID. Section 3 analyzes the performance behaviors of Linux software RAID (MD) and motivates the StRAID design. Section 4 describes StRAID's design. We evaluate StRAID in Section 5 and describe related works in Section 6. Section 7 concludes this paper.

2 Background

2.1 RAID Systems

Redundant Array of Inexpensive Disks (RAID) [56] is a classic system-level approach that combines multiple disks to improve performance, reliability and capacity simultaneously. Over the past decades, RAID has been used ubiquitously to construct and manage efficient storage servers, distributed storage [5, 54], and cloud storage [1, 38] from within and/or among storage devices.

The RAID architecture is categorized into various RAID levels based on the amount of redundancy and how redundancy is incorporated, including non-parity RAID (e.g., striping-only RAID0 and mirroring-only RAID1) and parity RAID (e.g., RAID5 and RAID6 that can tolerate one and two disk failures respectively). RAID can be implemented in either software or dedicated hardware (e.g., I/O controllers or firmware) to offer the block-addressable volume. A common N-disk RAID internally consists of multiple stripes, each of which comprises user data chunks and their corresponding parity data chunks across N disks according to an algorithmic address-mapping method. Normal reads without disk failure are directly decomposed to their constituent chunk I/Os served by the underlying disks. Normal writes in non-parity RAID behave like normal reads without accessing parity chunks.

Normal writes in parity-based RAID need extra parity generation, update, or construction operations. For a full-stripe user write where all data chunks of a stripe are written, the RAID system generates all new parity chunks at once, and then writes both data chunks and parity chunks into their corresponding disks. For a partial-stripe write where only a subset of the data chunks of a stripe are written, only after its constituent old data or parity chunks are read from the disks is the stripe updated and then written into the disks again, thus inducing numerous extra I/Os [9, 30]. This read-modify-write nature of partial-stripe writes makes them notoriously costly. When disks fail within the failure-tolerance range, the RAID transitions from its normal mode to a degraded mode to perform read, write, or resync operations.

2.2 Linux Software RAID

The Linux software RAID module, referred to as Multiple-Disk (MD) [45], is the most commonly used software RAID evolving with the Linux Kernel for over two decades. Currently, MD supports various RAID levels and RAID compositions. Non-parity-based RAID in MD perform an algorithmic

Figure 1: The throughput of Linux software RAIDs on three-types of SSDs under varying number of user threads.

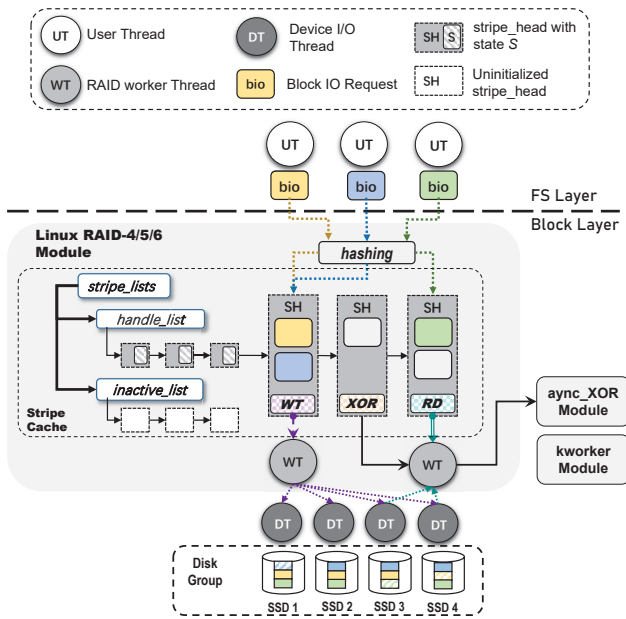

Figure 2: Architecture of Linux MD parity-based RAID.

block-to-chunk address mapping. For parity-based RAIDs, normal reads are similar to those in a non-parity-based RAID without parity operation. However, writes inevitably introduce several additional parity-generation/modification operations. Figure 2 shows the architecture of MD parity-based RAID and Figure 3 shows the workflow of their stripe-writes. The centralized data structure (stripe-cache) comprises inactive and handling stripe-lists, which maintain the metadata of the stripes (up to 256 by default). Each stripe has its own stripe_head containing stripe states and device states (*Devs*). *Devs* contains a set of block request structures (*bios*) pointing to their buffered pages. Specifically, a stripe and its corresponding *Devs* have 28 and 27 states respectively that are used to precisely identify the handling states of this stripe. When a stripe is processed and cleared, its corresponding stripe_head will be transferred into the inactive_list.

MD handles stripe-writes using a state machine represented as a directed acyclic graph (DAG) [17]. As shown in Figure 3, a normal user write process can be divided into 5 consecutive stages: 1) inserting/aggregating *bios* to a stripe (INS); 2) reading data/parity chunks (RD); 3) computing parity (XOR); 4) writing data/parity (WT); 5) clearing stripe (CLR). Specifically, in the first stage ①, user threads (*UT*) invoke *make_request()* to attach *bios* to their correspond-

Figure 3: Stripe-write workflow of parity-based MD RAID.

ing stripe_head structures. Afterwards, a daemon worker thread (*WT*), i.e., *RAID5d* in MD by default, handles all active stripe_heads in a circular manner with priority.

For a full-stripe write, MD skips the second stage. For a partial-stripe write, MD must introduce write-induced reads ②, resulting in I/O amplification. More specifically, there are two stripe-updating schemes, read-modify-write (RMW) and read-construction-write (RCW) [30]. MD calculates the required number of disk-read I/Os of both RCW and RMW, selects the I/O-minimum approach, and launches the relevant disk-read I/Os. When a disk I/O thread (*DT*) completes the read, it sets a data-prepared flag to its *bios*. Afterwards, ③ *WT* checks all the involved *bios* until prepared, and then launches a parity-calculation executed by other XORing threads. When *WT* verifies that the parity has been prepared, ④ it invokes disk-write I/Os. ⑤ *WT* finally validates the completed state and clears the stripe_head. Therefore, the write process orchestrates *WT*, *UT*, and *DT* threads via shared-state setting and checking.

WT handles each stage of a stripe-write in four steps, as described in Figure 3: ① getting a stripe_head from a stripe_list; ② analyzing the current state of this stripe and all its involved *bios*, to determine whether this stripe is still in-flight; ③ handling the stripe by launching a given operation (e.g., XOR) through executing DAG; and ④ updating the stripe state, inserting it back into a stripe_list and selecting the next stripe. The worker thread handling a stripe exclusively accesses shared data structures and stripe-states using multiple locks. For example, in step ④, *WT* exclusively modifies *handle_list* with a global device lock.

For HDD-based RAID, a disk I/O takes at least several milliseconds. Therefore, a *WT* in Linux MD has sufficient CPU-cycles to drive all stripe-writes. With the emerging SSDs that have 2-3 orders of magnitude lower I/O latency than HDD, MD also introduces a multi-worker mechanism [39,40] that enables more numbers of functionally equivalent worker

Table 1: Evaluation Platform Specifications

| Components | Configurations |
|------------------|---|
| Processor | Duel Socket Intel Xeon Gold 6328, 56 Cores, 128MB LLC |
| Memory | 256GB 2666MHz DDR4 |
| Operating System | Ubuntu 20.10 LTS with the Linux kernel version 5.13.0 |
| MD controller | mdadm v4.1 |

Table 2: Characteristics of three representative SSD products.

| Device Types | Device Modules | Capacity | Stable Write Thr. (MB/s) | Stable Read Thr. (MB/s) | Interfaces |
|--------------|-----------------|----------|--------------------------|-------------------------|------------|
| SATA SSD | Samsung 860 Pro | 512GB | 500 | 510 | SATA |
| NVMe SSD | Samsung 970 Pro | 512GB | 2200 | 3200 | PCIe 3.0 |
| NVMe SSD | Samsung 980 Pro | 1TB | 2600 | 6900 | PCIe 4.0 |

threads to process stripes concurrently, referred to as the N-for-all processing model.

3 Analysis and Motivation

3.1 Understanding the Write Performance

Experiment Setup We start with measuring the MD performance in the RAID0, RAID5 and RAID6 levels running on three types of SSD devices, whose I/O characteristics are listed in Table 2. The platform configuration is shown in Table 1. The XORing throughput on a single CPU-core can reach up to 29GB/s. We deploy six SSD devices to construct parity-based RAID5, that is, 5+1 RAID5 and 4+2 RAID6 respectively. The chunk size in all RAID5 is set to 64KB as default. We pin each user thread (UT) to a unique CPU-core and increase the number of UTs from 1 to 64. Each UT issues random 64KB-sized writes over 30 seconds. For parity-RAIDs, we invoke up to 64 extra RAID worker threads (WT), and enlarge the stripe cache capacity from the default of 256 stripe_heads to 16K stripe_heads.

Write Inefficiency with Parity-RAID Figure 1 reports the throughput performance of MD. In all the cases, the write performance and scalability of the non-parity RAID0 far exceed those of parity-based RAID5 and RAID6. RAID0 achieves a write performance of about 1.4GB/s and 11GB/s peak throughput on 860Pro and 980Pro SSDs at 64 UTs, while RAID5 in the multi-worker mode achieves a peak write performance of lower than 0.72GB/s and 5.3GB/s, respectively. On 980Pro, the 64KB partial-stripe write throughputs of parity-RAIDs are below 2.1GB/s, which is only 1/7 of that of RAID0. Even for the 1MB full-stripe writes, the throughputs of RAID5 and RAID6 with 64 UTs are below 5.2GB/s and 5.3GB/s respectively, only about 38% of that of RAID0. It indicates that parity-RAIDs fall short of leveraging the write I/O performance of modern SSDs and the bottleneck on CPU processing is the main reason. We will show more details in the next section. Besides, normal reads of MD in all RAID levels are generally similar and scale well with the number of UTs.

We further analyze the write inefficiency of the multi-worker mechanism with RAID5 on six 980Pro SSDs. We invoke 64 UTs in either the single-worker (i.e., *Single*) mode or the multi-worker mode with the number of WTs vary-

Figure 4: Write throughput of MD RAID5 under the multi-worker mechanism.

Table 3: Key function calls and locks of Linux parity-RAID.

| Operations | Function as example | Description |
|------------|----------------------------|---|
| RD/WT | generic_make_request() | Send bio to block device queues (Ⓜ in stages Ⓜ and Ⓜ) |
| XOR | async_xor() | Compute parity data (Ⓜ in stage Ⓜ) |
| F/R List | release_stripe() | Insert the stripe_head to stripe_list according to its states (Ⓜ and Ⓜ) |
| Lock | spin_lock_irq(device_lock) | Global MD device Lock, mainly used for updating shared structs |
| Analyze | analyze_stripe() | Analyze the states of a stripe and its Devs before handling (Ⓜ) |
| Others | - | Other software overhead |

ing from 1 to 64 (i.e., +1W to +64W). Figure 4 shows that the parity-based RAID gains limited benefits from the multi-worker mode. For example, MD with 8 more WTs has a write throughput improvement of 2.4x and 3.6x over the single-worker mode under 16 and 64 UTs, respectively. However, MD’s performance gain peaks at 16 WTs, beyond which MD’s throughput starts to gradually decrease, e.g., with a 5% decline at 64 WTs. This indicates that the multi-worker mode has a diminishing return in performance beyond a relatively small number of WTs. Therefore, even in the case of 64 UTs and 64 WTs, parity-RAIDs still fall short of fully leveraging the I/O bandwidth offered by the fast SSDs.

3.2 Identifying the Root Causes

We investigate the CPU usage distribution to identify the root causes of poor write scalability of MD. We use RAID5 with fixed 64 UTs and vary the number of WTs from 1 to 64. We use perf [44] to measure CPU cycles of key functions within a WT thread, detailed in Table 3. We randomly select one WT for analysis since all WTs behave very similarly in our experiments. Figure 5 shows that CPU cycles of disk I/O (RD/WT) and XORing (XOR) decrease as the number of WTs increases, accounting for 42% of the total CPU cycles in the single-worker mode, but only 9.7% at 64 WTs. Meanwhile, the CPU cycles of stripe-write process (i.e., F/R List, Lock, Analyze and Others) increase significantly as WTs increase.

First, the global device lock (Lock) consumes a mere 4.3% of CPU-cycles in the single-worker mode but a dominant 54.6% in the 64-worker mode. As shown in Table 3, the device lock in Linux MD is spin lock, which controls concurrent accesses from WTs, UTs, and DTs to all the stripe_lists and metadata of RAID. In most cases, each WT exclusively accesses the handle_list, thus causing severe lock contention

Figure 5: Breakdown of CPU cycles on key functions and locks of the worker threads in Linux MD.

among these threads. Recently, Linux Kernel contributors also found high overhead of the device lock in the read path [52] and replaced them with a lockless memory barrier, thus achieving 7x improvement in small-sized reads. However, the device lock in the write path remains a serious source of contention.

Second, checking for stripe states (*Analyze*) consumes 22% and 13.2% CPU usage in the single-worker and 64-worker modes, respectively. In Linux MD, most of the stripe states and device bio states use a set of semaphores to orchestrate UTs, WTs, and DTs. In summary, through extensive experiments, we observe that the architectural deficiency of the N-for-all centralized handling model leads to severe lock contentions due to highly-concurrent accesses to global data structures and the states of stripes.

4 Design

Given the above identified root causes of write inefficiency of MD with parity-RAIDs running on ultra-fast SSDs, we propose a stripe-threaded architecture of parity-RAID, StRAID for short. StRAID assigns a dedicated worker thread for each stripe-write, which significantly reduces lock contentions among multiple threads, and addresses the partial-stripe-write penalty with a two-phase write submission and a parity cache.

4.1 Architecture

Figure 6 illustrates the StRAID architecture for parity-RAID. StRAID does not change the data layout of the legacy MD. It persists RAID’s metadata at the pre-defined location of each disk. Each user thread (*UT*) pushes a block-write to a dedicated worker thread (*WT*) that exclusively handles its corresponding stripe. Multiple WTs process their own stripes independently, exploiting the intrinsic data parallelism among stripes. StRAID pre-allocates at least 256 WTs in the WT Pool to alleviate frequent thread creation/destroy overhead in runtime.

A normal stripe-write process in StRAID can be divided into 6 consecutive stages of ① initializing stripe_heads and inserting bios (*INS*); ② reading parity/data chunks (*RD*); ③ performing I/O batching (*BAT*); ④ computing parity (*XOR*); ⑤ writing data/parity and ⑥ clearing stripe states in SST (*CLR*). Moreover, ⑦ user threads being batched must wait for completion (*WAIT*). A notable workflow difference between StRAID in Figure 6 and the legacy MD in Figure 3 is that

Figure 6: Architecture and process flow of StRAID

the latter’s stages of ① stripe acquisition, ② analysis and ④ stripe release are removed in the former.

Compared to the legacy MD, StRAID removes the centralized stripe_head lists and their corresponding concurrent operations. Furthermore, StRAID minimizes the number of shared stripe-states and global-state checking among WTs, because a dedicated WT handles a stripe-write exclusively. Finally, the parity computation and I/O execution processes of a stripe write are pinned to the same CPU core, thus avoiding frequent context switches and CPU cache pollution.

However, StRAID faces new challenges in effectively conducting thread collaboration and reducing the partial-write penalty. StRAID still needs a minimal shared-data structure to orchestrate UTs, WTs, and DTs in handling stripe-writes. To this end, StRAID proposes a Stripe State Table (§4.2) with lockless access features. Further, the legacy MD uses the global stripe-cache and active/passive delays to aggregate stripe-associated writes (SS-writes) that target the same stripe, thus reducing partial-write-induced disk I/Os. However, in StRAID, a user write triggers a dedicated WT to immediately and exclusively handle the corresponding stripe-write, which does not address the costly partial-write penalty. To optimize partial-stripe writes, StRAID presents a two-phase stripe submission mechanism (§4.3) to opportunistically aggregate SS-writes by employing a batching queue per WT. Further, StRAID employs a parity cache (§4.4) in memory to buffer hot parity blocks, for significantly mitigating write-induced parity-reads.

4.2 Stripe State Table

StRAID designs a Stripe State Table (SST), as shown in Figure 7, to maintain a minimal set of shared stripe-states.

Figure 7: Stripe state table.

SST adopts a hash table to index up to 4096 active stripe-entries, each of which is handled by a dedicated worker thread. An SST-entry (48-bit) contains four fields: 32-bit *Stripe ID* uniquely specifying a stripe; 1-bit *Stripe Lock* indicating whether this stripe is currently being processed; 14-bit *TID* identifying the thread ID of the dedicated WT handling this stripe; and 1-bit *is_frozen* recording the shared stripe-state that indicates whether the stripe is allowed to batch. SST is a globally shared structure between WTs and DTs, where each entry is uniquely associated with a physical stripe and can only be exclusively modified by a WT using CAS [57] at any time. SST employs Cuckoo hashing [53] for achieving high table occupancy while preventing hash collisions. The total memory footprint of SST is smaller than 40KB.

4.3 Two-phase Stripe Submission

Partial-stripe Write Overhead A partial-stripe write causes write-induced reads and write amplification. The write-induced-read ratio (*WIRR*) and write amplification (*WA*) of RAID5 are estimated by Eq.1 and Eq.2 respectively, where *WS*, *CS* and *SS* represent write-size, chunk-size and stripe-size, respectively. When *WS* is smaller than *CS* in RAID5, a block-size write induces 2x read I/Os and 2x write amplification (one data-block write and one parity-block write) with optimal RMW strategy. As *WS* increases, the amount of write-induced-read data decreases (0 for a full-stripe write). The write amplification is larger than 1.2x on RAID5 with no disk failures.

$$\text{Write-induced-read Ratio} = \begin{cases} 2 & WS \leq CS & (RMW) \\ 1 + \frac{CS}{WS} & CS \leq WS < \frac{SS}{2} & (RMW) \\ \frac{SS}{WS} - 1 & \frac{SS}{2} \leq WS < SS & (RCW) \\ 0 & WS = SS \end{cases} \quad (1)$$

$$\text{Write Amplification} = \begin{cases} 2 & WS \leq CS \\ 1 + \frac{CS}{WS} & WS > SS - CS \end{cases} \quad (2)$$

Existing optimizations for partial-stripe writes can be characterized by the three general approaches of write-aggregation [45], dynamic stripe size [7, 76], and parity logging [9, 10, 15, 71, 72]. The legacy Linux MD employs a global stripe-cache to absorb active user writes by postponing stripe-writes actively or passively. This write-aggregation approach reduces actual disk I/Os but increases the latency of the postponed requests, which may hurt the overall performance for low-latency SSDs. RAIDZ [7] uses a dynamic stripe size mechanism to eliminate partial-stripe writes, but assumes the support of the ZFS file system. The logging approach first persists incoming writes to an auxiliary fast-disk (e.g., SSD

or NVM), and then rewrites the relevant stripes to original locations in the background, thus leading to at least 2x write amplification and bottlenecks from log-devices.

Two-phase Stripe Submission Without a global stripe-cache, StRAID designs a two-phase stripe submission mechanism to opportunistically absorb SS-writes. StRAID divides the stripe-write process into two phases: a batching phase and a frozen phase. Specifically, Figure 8 (referred by circled numbers) and Algorithm 1 (referred by line numbers) describe the two-phase submission using an example where three concurrent I/O threads issue requests targeting the same stripe (*SI*). A worker thread 1 (*WT1*) receives bios from its corresponding UT, and acquires a stripe lock to begin stripe processing (*Time* ①, *line* 2) by CAS operation. *WT1* first initializes the stripe states in SST, then it determines the reconstruction method (RCW/RMW) for this stripe and reads the required parity/data blocks from the disk (*line* 4-6). Shortly after *WT1*'s arrival, a second worker thread (*WT2*) arrives and seeks SST, only to find that the targeted stripe is locked but enables batching (*Time* ②, *line* 14). It inserts bios belonging to this stripe to the batching queue of the handling thread *WT1* (*Time* ③, *line* 15) and then suspends itself.

When *WT1* completes its batching phase, it immediately transitions the stripe into the frozen phase (*Time* ④, *line* 7) by using the CAS operation. At this point, the stripe is not allowed to accept new bios. Hence, the newly arrived bios from worker thread 3 (*WT3*) (*Time* ⑤) are blocked and have to wait for the stripe write's completion. *WT1* coalesces all requests in its batching queue and processes them as a whole, then it re-executes parity read (if required) in accordance with the aggregated stripe-write, and performs XORing and data/parity writes to reconstruct the stripe. Finally, *WT1* clears up the stripe states of *SI* in SST and releases the stripe lock. The corresponding waiting thread *WT2* will also return successfully (*Time* ⑥, *line* 12). Next, *WT3* successively acquires the *Stripe Lock* to handle its requests on the stripe.

In contrast to the stripe-cache approach for aggregating SS-writes used in Linux MD, the novelty of the two-phase writing approach in StRAID leverages the latency of executing a reconstruction read in the batching phase to opportunistically aggregate incoming SS-writes. It ensures the efficiency of each handling thread, thus achieving better throughput without sacrificing I/O latency.

4.4 Parity Cache

Partial-stripe writes induce frequent parity-block accesses and cause performance degradation. To alleviate this problem, StRAID further designs a parity cache to keep hot parity-blocks in the memory to reduce disk I/Os. Previous works [9, 63, 72] use the logging approach to absorb parity updates at the cost of write amplification and potential bottlenecks at the log-devices. StRAID, instead, uses the parity cache only for eliminating parity reads induced by partial-stripe writes.

Algorithm 1 Two-phase stripe submission

```

1: while all bios are handled do
2:   if get_stripe_lock(stripe_id) then
3:     init_SST(stripe_id)
4:     Determine reconstruction method
5:     if is_partial-stripe write then
6:       read from disks
7:       set is_frozen = true in SST and pull batching bios from queue
8:       if Data is not enough for reconstruction then
9:         Re-read from disks
10:      Compute XOR and reconstruct stripe
11:      clear_SST(stripe_id)
12:      release_stripe_lock(stripe_id)
13:   else
14:     if !is_frozen(stripe_id) then
15:       insert bio to queue with TID
16:     else
17:       handled = false
18:       continue
19:   Waiting for all bios to complete

```

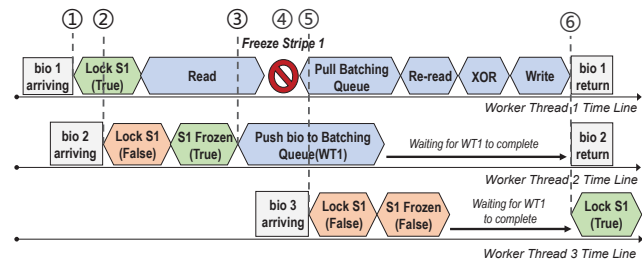

Figure 8: Workflow of two-phase stripe submission, an example with 3 concurrent worker threads (*WT1-WT3*) targeting the same stripe.

The stripe parity has higher access-frequency than its stripe data for partial stripe writes. Therefore, caching parity data is significantly valuable.

The architecture of parity cache is shown in Figure 9. It contains a high concurrency hash table with $O(1)$ lookup cost, and uses an LRU-based cache replacement policy to capture frequently accessed parity data. Each hash entry corresponds to a physical stripe and contains three fields, *Stripe_ID*, *p_data* and *q_data* with the latter two pointing to cached parity data aligned with the 4KB block size. RAID5 only uses the *p_data* pointer and RAID6 uses both pointers. In addition, each entry has a fine-grained read-write lock for synchronization.

The cache module updates and queries at the block granularity, but inserts and deletes hash entries at the stripe granularity. For updates and queries, a WT needs to first insert the *Stripe_ID* into the LRU and searches the relevant entry. The read lock is required to access cached data because each stripe can only be updated exclusively by one WT. During the stripe-write process, a WT first searches the parity cache and acquires hit parity blocks. When missed, WT updates both disks and cache in a write-through scheme with the newest parity data after XORing.

StRAID periodically triggers a dedicated thread to clean up the stripe in the background. When the cache size exceeds

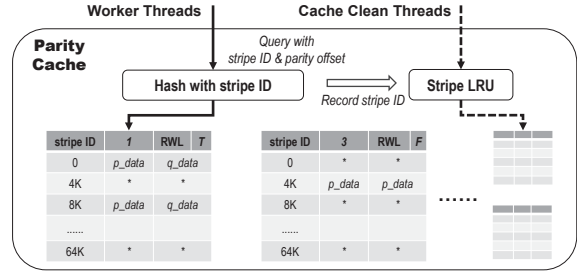

Figure 9: Architecture of the parity cache.

a threshold (64MB capacity for 16K parity blocks as default), the cleaning thread removes the entries of evicted stripes from the cache according to the LRU policy.

4.5 Recovery and Degraded Mode

Crash Consistency and Recovery After a system crash, part of the chunk writes belonging to a stripe-write may be lost, making the stripe inconsistent between its data and parity. StRAID uses a bitmap to record the current update-state of each chunk. Compared with Linux MD, StRAID’s bitmap has basically the same data structure and layout, but can only be updated and flushed by dedicated threads. For each chunk update, StRAID first sets the corresponding bitmap bits and changes their involved memory-page as dirty, then flushes the page to the underlying SSDs via the memory mapping mechanism. The bits will be cleared after their corresponding chunks are written to the disk. Similar to MD, StRAID groups bitmap updates in a batch to avoid frequent disk I/Os. In the experiment, it is found that flushing the bitmap only incurs a very small overhead (less than 2%) when handling stripe writes. With unexpected power failures, StRAID will fetch the bitmap from the disks and restore it to the consistent state after reboot. Moreover, StRAID has the option to use a journal device [3] as a writeback cache to prevent the write hole problem [22].

Resync and Degraded Mode StRAID supports degraded reads, degraded writes and resync operations in the same way as the legacy MD because the underlying data layout is identical. For stripe writes, StRAID identifies the degraded stripe and handles it after entering the frozen phase. The resync operation reads all the data blocks from disks and compares their calculated parity results with their on-disk parity data. It is triggered upon RAID initialization, or reconstruction from disk replacement. We evaluate the performance of StRAID in degraded mode in Section 5.

5 Evaluation

5.1 Evaluation Setup

Platform We run all experiments on a server (detailed settings listed in Table 1) and three types of SSD devices (described in Table 2). The CPU-core can reach 29GB/s XORing

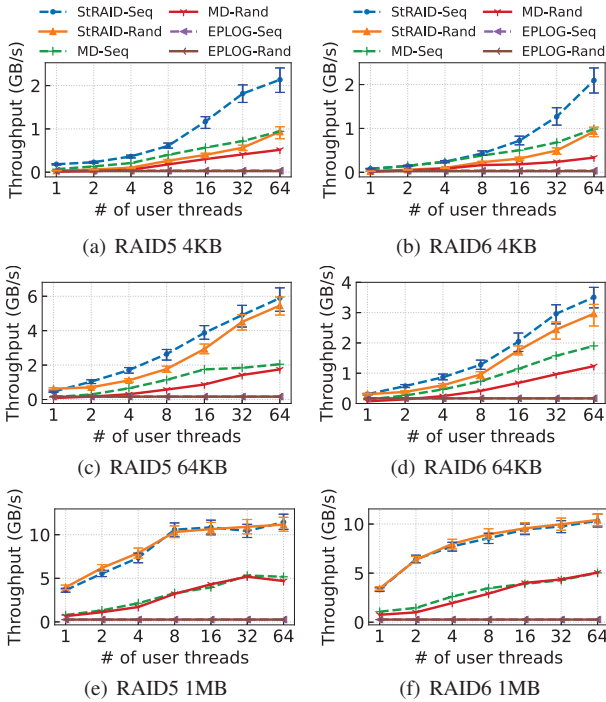

Figure 10: Write scalability on three different RAID systems.

Figure 11: Read scalability of StRAID and MD.

throughput and the PCIe I/O bandwidth is 48GB/s [21], exceeding the aggregate sequential bandwidth of 6 NVMe-based SSDs (2.6GB/s stable write throughput per SSD, 15.6GB/s in total). In our experiments, we bind all the I/O threads and worker threads to the same CPU socket-0 to avoid remote accesses of memory and PCIe, i.e., the NUMA issues.

RAID systems setup We evaluate StRAID and Linux MD (MD) of the RAID5 (5+1) and RAID6 (4+2) levels built on 6 SSDs. The chunk size is set to 64KB by default. StRAID has a 64MB-sized parity cache. Linux MD has a 16K-entry stripe-cache and up to 64 worker threads. This is a setting that MD is shown by our experiments to achieve the best throughput. In addition, we compare StRAID with EPLOG [9] that mitigates parity update overhead by redirecting parity traffic to separate dedicated HDD logging devices. To prevent the log-devices from becoming a bottleneck, we replace the HDDs of EPLOG with the same type of SSDs used in the main RAID array.

Workloads We implement a program to issue direct block I/O requests with sequential or random access patterns as micro-benchmark. We run each experiment ten times and take the average as the results. We further select six representative block traces summarized in Table 4 as trace-driven

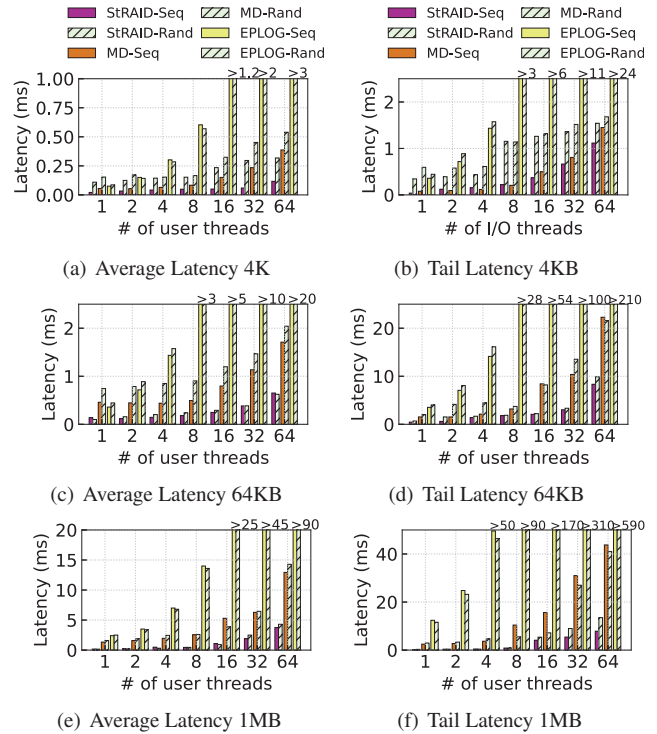

Figure 12: Average and tail latency of RAID systems.

macro-benchmarks. We implement a trace player in C++ using POSIX sync to generate direct block I/O requests to the underlying RAID systems.

5.2 Micro-benchmark

We measure the write throughput, average and tail latency, and amount of disk read/written data on MD, StRAID and EPLOG with RAID5 and RAID6 on 980Pro SSDs, respectively. We generate workloads with a different number of concurrent I/O-issuing threads (i.e., UTs) and varying access patterns. Three default I/O sizes are: 4KB (default block-size of file systems, page cache, and block devices), 64KB (partial-stripe write size), and 1MB (full-stripe write size).

Throughput Figure 10 reports the write throughput of StRAID, MD and EPLOG in RAID5 and RAID6, respectively. The errorbars are added on StRAID’s results. The throughput of StRAID exceeds that of MD and EPLOG respectively by up to 2.1x and 1.4x with 4KB-sized writes and 1.5x and 1.3x with 64KB-sized writes with a single UT, respectively. This is because StRAID effectively reduces the overhead of handling stripe-states. As the number of UTs increases to 64, StRAID achieves up to 2.0GB/s±0.2GB/s and 6.0GB/s±0.8GB/s peak throughput with 4KB and 64KB writes respectively, representing 2.1x/59.1x and 2.9x/35.1x performance improvement over MD/EPLOG. In addition, EPLOG achieves 1.4x-1.9x higher throughput than MD under random write at a single UT, because it avoids partial-write-induced reads with parity-logging. However, EPLOG does not scale at all with more

Figure 13: Breakdowns of CPU cycles on StRAID and MD

Figure 14: Total CPU utilizations

Figure 16: StRAID and MD throughput with partial-stripe (*-P) and full-stripe writes (*-F) of different chunk sizes.

Figure 15: Amount of data written to and read from disks by StRAID, normalized to that of MD.

UTs, because it uses a global lock for serializing each write operation.

For full-stripe writes (i.e., 1MB), StRAID achieves 4.6x/12x and 5.2x/13x higher write throughput in random and sequential cases than MD/EPLOG with a single UT, respectively. As the number of UTs increases to 8, StRAID’s throughput saturates the device bandwidth, with an almost fixed increase of about 6GB/s over MD. With 64 UTs, the peak write throughput reaches 11.4GB/s±1.1GB/s and 10.4GB/s±1.0GB/s in StRAID under RAID5 and RAID6 respectively, which are 2.1x higher than those of MD (5.2GB/s and 5.1GB/s) and 41x higher than EPLOG (0.25GB/s and 0.26GB/s). StRAID’s full-stripe writes nearly unleash the full power of the SSD performance, while MD suffers from heavy contention on the global data structures.

Moreover, Figure 11 shows the read throughput of StRAID and MD with varying-size reads. The average read throughput difference between MD and StRAID is less than 5% in RAID5 and RAID6 respectively, demonstrating that StRAID does not affect read performance.

Latency and Breakdown of CPU-cycles Figure 12 shows the average and tail (99th-percentile) latency under RAID5 in StRAID, MD and EPLOG, respectively. StRAID significantly outperforms MD and EPLOG in both average and tail latencies performance under 64 UTs, reducing latency by 75% and 98.2% with 4KB block-writes, 76% and 97.1% with 64KB partial-stripe writes, and by 69% and 95.2% with full-stripe writes. StRAID reduces 22%-67% tail latencies from MD under 64 UTs. The tail latency of EPLOG is 6.5x-42.1x higher than StRAID under multiple UTs, since the global lock in EPLOG makes its average and tail latencies much higher than those of MD and StRAID.

To better understand the reasons behind StRAID’s superiority, Figure 13 shows the breakdown of the CPU-cycles of key functions consumed by MD and StRAID with 64 UTs issuing random writes, respectively. For partial-stripe writes, the combined CPU-cycles on XORing and disk I/Os account

Table 4: Characteristics of block I/O traces used in the macro-benchmark evaluations

| Trace | Write Ops (millions) | Data Written (GB) | Avg.write size (KB) | Read Ops (millions) | Data Read (GB) | Avg.read size (KB) |
|-----------|----------------------|-------------------|---------------------|---------------------|----------------|--------------------|
| Pangu-A | 1.89 | 113.24 | 63.21 | 0.24 | 4.06 | 17.99 |
| Pangu-B | 2.44 | 81.32 | 35.08 | 0.30 | 18.61 | 65.24 |
| prxy_0 | 12.14 | 53.80 | 4.65 | 0.38 | 3.05 | 8.33 |
| prn_0 | 4.98 | 45.97 | 9.67 | 0.60 | 13.12 | 22.84 |
| varmail | 3.39 | 39.20 | 12.13 | 0.05 | 5.38 | 114.05 |
| filesrver | 1.19 | 99.45 | 87.56 | 0.47 | 42.37 | 95.49 |

for 76% of the total CPU usage in StRAID, while that of MD is less than 20%. The average stripe-write handling overhead of StRAID, i.e., 60μs, is about 20 times less than that of MD, i.e., 1180μs. Besides, the lock overhead on StRAID and MD account for 5.1% and 46.1% of the total CPU usage, respectively. StRAID efficiently mitigates lock contentions through the stripe-threaded architecture and the lockless access features in SST.

For full-stripe writes, the lock, XORing and I/O-write of StRAID account for 1.3%, 22.5% and 62.6% of the total CPU usage, respectively, in contrast to their MD counterparts of 36.7%, 24.5% and 19.4%, suggesting that StRAID achieves to make better advantage of SSDs’ high write bandwidth. In addition, the two-phase submission and the parity caching use only 6% and 1.5% of the stripe-write CPU-cycles of partial-stripe and full-stripe writes, respectively.

CPU utilization We compare the CPU utilizations of StRAID and MD under random full-stripe and partial-stripe write workloads respectively, with the same RAID5 settings in Figure 10. Results in Figure 14 show that the total CPU utilization of MD is up to 6.3x higher than StRAID with 64 UTs. Even when the number of UTs is less than 8, the CPU usage of MD is 2x higher than that of StRAID on average. Combining with the throughput results shown in Figure 10, MD with 4495% CPU-core utilization consumes only 1/3 of the SSDs bandwidth, in contrast to StRAID that consumes 86.9% of the SSDs bandwidth with 1156% CPU-core utilization.

Moreover, 64KB-sized partial-stripe writes of MD (MD-64K) consume up to 80% more CPU than full-stripe writes (MD-1M) with 64 UTs. MD’s inefficiency stems from its high consumption of CPU cycles required to handle in-flight partial-stripe writes. On the contrary, StRAID-64K consumes only 25% less CPU cycles than StRAID-1M because StRAID gains higher throughput for full-stripe writes that consumes more CPU resources for computing XOR and issuing I/Os.

Read/Write amplification Figure 15 shows the amount of

Figure 17: Throughput of StRAID and MD on trace-driven workloads.

Figure 18: Latency CDF of StRAID and MD on trace-driven workloads.

data written to and read from disks by StRAID in RAID5, normalized to that of MD. For random writes, StRAID and MD have exactly the same amount of data written and data read because stripe-write aggregation is rare for random writes. For sequential writes, however, the amount of data written in StRAID is up to 12% larger than MD. This is because the two-phase submission in StRAID has a smaller aggregation window (i.e., proportional to SSD-read latency), which is slightly less efficient than Linux MD’s active delays of sequential stripe writes.

For sequential writes, the amount of data read in StRAID and MD varies significantly with different numbers of UTs. With a single UT, the amount of read data in StRAID is 1/2 of that in MD, because the parity caching mechanism effectively reduces parity reads. However, with 64 UTs as the worst case, StRAID reads 12x more data than MD. It is because MD postpones and aggregates almost all stripe-associated writes (SS-writes) into full-stripe writes, thus reducing the amount of write-induced-read data (e.g., 1.1% of user-written data). In contrast, a StRAID’s worker thread immediately executes reading parity/data chunks before performing write-aggregation, resulting in a nearly fixed number of write-induced reads (e.g., 13.7% of user-written data). However, since the high read IOPS of fast SSDs can completely absorb the increased number of read I/Os, StRAID’s write performance can still be 5.2x higher than MD.

Chunk Sizes We evaluate the effect of chunk size configuration on the performance of StRAID and MD with 64KB-sized writes in RAID6. The chunk size is set to 8KB for the full-stripe-write case (*StRAID-F* and *MD-F*), and 64KB for the partial-stripe-write case (*StRAID-P* and *MD-P*), respectively. Figure 16 shows that both StRAID and MD benefit significantly from full-stripe write workloads. The throughput of StRAID-F reaches 11.8GB/s with 64 UTs, about 1.9x higher than StRAID-P. Similarly, the throughput of MD-F is up to 3.1x higher than MD-P. However, the peak throughput of MD-F (8KB chunk size and 64KB write size) remains at 5.3GB/s, consistent with the results shown in Figure 1(d) (with 64KB chunk size and 1MB I/O size). It indicates that the peak throughput of StRAID is sensitive to the chunk size

setting. An insight from this experiment is that it is beneficial to set StRAID’s chunk size smaller, such as 8KB, to take full advantage of full-stripe writes.

5.3 Macro-benchmark

We use six representative block traces from Filebench [60], cloud-based application traces from Alibaba-Pangu [47] and Microsoft [51] to evaluate StRAID’s performance. Table 4 summarizes the characteristics of these workloads, most of which are read-write mixed or write-dominated. In the experiments, we enable 32 WTs in MD and StRAID, and evaluate them in both the RAID5 and RAID6 levels with a chunk size of 8KB. We invoke 32 user threads to replay these traces continuously, mimicking high-intensity workloads.

Figure 17 shows the throughput of StRAID and MD over time. StRAID achieves up to 2.8x higher throughput than MD, and shortens the total running time by an average of 64% across 6 workloads. In the fileserver workload, StRAID achieves peak and average throughput of 10.3GB/s and 7.9GB/s respectively, in contrast to their MD counterparts of 5.0GB/s and 3.2GB/s. The fileserver workload has the largest average write size, so that StRAID benefits from full-stripe writes. For the cloud-based workloads, StRAID’s average throughput is 3.1x and 3x higher than MD’s in Pangu-A and Pangu-B, respectively. The prxy0 workload exhibits the lowest average throughputs among all workloads, 1.8GB/s and 0.6GB/s for StRAID and MD respectively. This is because the prxy0 trace has the smallest average write size (i.e., 4.6KB) among all workloads, leading to a large amount of partial-stripe writes for both StRAID and MD. Further, it is observed that StRAID in RAID5 is 10%-15% better than in RAID6 among all the workloads, because RAID5 has less parity data than RAID6.

Figure 18 shows the latency CDFs of StRAID and MD across all the workloads. StRAID shows significantly better CDF profiles, with about 80% and 69% lower average latency than MD in workloads Pangu-A and Pangu-B, respectively. For the other four workloads, StRAID also has at least 49% lower average latency than MD. The median latencies of

Figure 19: Performances of StRAID and MD on different SSDs and RAMs.

Figure 20: StRAID throughput with partial-stripe (*-P) and full-stripe writes (*-F) when running with/without two-phase stripe submission (w/ TPS and w/o TPS).

StRAID in workloads Pangu-A, Pangu-B and filebench are almost ten times lower than MD, while for workloads varmail, prn0, and prxy0 StRAID’s is 78%, 74% and 75% lower than MD’s respectively. The 99th-percentile tail latency in StRAID is 25% lower than that in MD among all workloads on average. For example, StRAID’s tail latency is up to 31.1% and 31.9% lower in workloads Pangu-A and prn0. StRAID’s advantage over MD in tail latency is lower than in average latency, because the high tail latency of both StRAID and MD mainly comes from write latency spikes caused by internal maintenance operations (e.g., garbage collection) within the SSD devices.

5.4 Sensitivity Study

Experiment with other devices Next, we evaluate the sensitivity of StRAID and MD to different types of storage devices. We first build StRAID and Linux MD on six Intel Optane PMs (in AppDirect Mode) [28] and lower-performance 970Pro SSDs, and compare these performances with that in 980Pros. The raw read and write bandwidth per PM can reach 6GB/s and 2GB/s [74], respectively. Further, we test the extreme RAID performance over six ramdisks on 128GB DRAM. We invoke up to 64 UTs with 64KB write-size for partial-stripe write-load and 1MB for full-stripe write-load.

Results in Figure 19 show that StRAID on 980Pro SSDs exhibits up to 20% higher throughput than it on 970PRO SSDs. In contrast, the performance difference of Linux MD on these two different types of SSDs is less than 5%. The throughput of StRAID on PMs is up to 50% and 35% higher than MD on partial-stripe and full-stripe writes, respectively. We also find that StRAID on PMs shows up to 26% higher throughput in partial-stripe writes than that SSDs. This is because PM has one order of magnitude lower read latency than SSDs, thus StRAID could handle stripes more efficiently.

Table 5: Parity cache capacity

| | Written Data (GB) | Read Data (GB) | Cache Hit Rate | Average Thr. (MB/s) |
|-------------|-------------------|----------------|----------------|---------------------|
| StRAID-NC | 54.10 | 13.64 | - | 1482 |
| StRAID-4M | 54.10 | 12.12 | 0.39 | 1593 |
| StRAID-16M | 54.10 | 12.01 | 0.45 | 1636 |
| StRAID-64M | 54.10 | 11.75 | 0.55 | 1711 |
| StRAID-256M | 54.10 | 11.23 | 0.57 | 1726 |
| MD | 53.80 | 6.10 | - | 667 |

Figure 21: Read and write performance on degraded StRAID and Linux MD.

Moreover, StRAID on PM shows a throughput drop at higher than 8 UTs, because PM has a limited concurrency [74].

In addition, StRAID on RAMs delivers up to 5.8x higher write throughput than MD. At 64 UTs, StRAID reaches up to 35.2GB/s random write throughput and 32.7GB/s sequential write throughput, respectively, in contrast to their MD counterparts of 5.8GB/s and 5.7GB/s. It shows that StRAID has the potential to effectively exploit faster storage like the emerging PCIe 5.0 SSDs [18] in the near future.

Two-phase Submission We analyze the performance contributions of the two-phase stripe submission (TPS) mechanism of StRAID in RAID5. We run the experiment with (w/ TPS) and without (w/o TPS) two-phase submission, respectively. The request size is set to 1MB for the full-stripe-write case (*-F), and 64KB for the partial-stripe-write case (*-P). We issue requests with sequential access patterns. Figure 20 shows that StRAID with TPS achieves 3.5x improvement of average throughput than without TPS for partial-stripe writes at 64 UTs. The two-phase submission allows request aggregation on writes belonging to a same stripe and handles them in a batch. StRAID without TPS, by contrast, has to individually execute each writes on a stripe. Besides, the performance contribution of two-phase submission on full-stripe write load is less than 4%, because the requests targeting different stripes will not be aggregated.

Parity Cache We analyze the effectiveness of the parity cache on StRAID performance. We compare the StRAID with the parity cache disabled (StRAID_NC) against the StRAID with its parity cache capacity varying from 4MB to 256MB (StRAID_4M to StRAID_256M). We select the RAID5 level with 8KB chunk size as an example. We run the prxy0 workload with the most partial-stripe writes among all workloads tested, which has 9.5% write operations (0.51 million ops) with I/O sizes of 40KB or larger (i.e., full-stripe write size for 8KB chunk size), and the sequential write ratio is 66% (8.02 million ops). We measure the average throughput, cache hit rate, and amount of disk read/written data, respectively.

Results are shown in Table 5. As the parity cache capacity increases, the cache hit ratio increases from 39% at StRAID-4M to 57% at StRAID-64M, resulting in a 16% improvement of average throughput. In addition, increasing the cache capacity to beyond 64MB contributes less than a 5% increase in both the cache hit ratio and throughput, because the cache has captured most of the parity data under such conditions.

5.5 Resync and Degraded Mode

We assess the performance of StRAID and Linux MD in the degraded mode under RAID5. One random SSD in the RAID array is set as failed. Then, a varying number of UTs issue reads and writes of 64KB and 1MB size, respectively. Results in Figure 21 show that the read throughput of degraded StRAID and Linux MD is almost the same, with an average difference of less than 5%. Meanwhile, the write performance of degraded StRAID is 50-70% higher than that in Linux MD with multiple UTs. This is because the processing flow of write operation in degraded mode is basically the same as that in the normal mode. In addition, StRAID and MD apply the same resync approach.

6 Related Works

SSD-aware RAID SSD-based RAID systems have been extensively studied and can be roughly classified into three groups: 1) taming tail-latency by alleviating GC impact [33,68,69,73]; 2) enhancing data reliability by optimizing parity distribution or conducting wear leveling across SSDs [4,41,65]; and 3) mitigating the overhead of parity writes [9,15,26,31,72]. StRAID focuses on the multi-threaded processing architecture in RAID systems and can complement these works.

All-Flash-Array Systems RAID for AFA (all-flash-array) systems have been studied for RAID data layout optimization [50,75] and taming tail-latency by alleviating GC impact [33,59]. FusionRAID [30] improves the latency performance of the RAID system for SSD pools by leveraging the Latin-square-based deterministic addressing methods proposed in RAID+ [75], while proposing an out-of-place write method for optimizing parity-updates. SWAN [33] tames tail-latency by alleviating SSD GC impact in an all-flash-array system. Complementary to them, StRAID focuses on the stripe-write process on multi-core processors and fast SSDs without any modification of the RAID data layout. Therefore, StRAID as a new stripe-handling engine can be used in AFA systems to exploit modern hardware with high internal parallelism.

Parity Write Optimization The stripe aggregation method is widely studied to construct full-stripe writes for reducing the write-induced reads or reducing the number of parity writes to SSDs. Previous works [15,16,26,63,72] use an NVRAM or SSD as a cache to absorb incoming write data and/or parity information and delay parity updates with extra devices. In contrast, the parity cache in StRAID is located in memory and only used to accelerate read I/Os for stripe

reconstructions. Existing systems [20,30,67] first steer all writes to a logging zone and then write back to the RAID zone in the background. Such an aggregation approach requires additional storage and double the amount of data written to SSDs. In comparison to these efforts, StRAID performs an in-place update for stripe writes and opportunistically aggregates writes without extra storage requirements.

Block IO Scheduling Prior studies on block IO scheduling are focused on optimizing multi-queue management including prioritization [37], fairness queuing [24,77], policy-based storage provisioning and management [2,62] and providing low scheduling latency [25]. StRAID is a RAID stripe-write engine on top of and thus complementary to these block IO scheduling approaches. Additionally, compared with other RAID systems that adopt FTL-level block I/O scheduling [34,66,78], StRAID considers SSDs as black boxes, making it highly portable and non-intrusive.

Multicore Optimization Previous studies have addressed the scalability issues in key-value stores [12,13], file systems [6,14,43], volume management [36] and block drivers [25] with multicore processors and high-performance devices (e.g., SSDs and NVMe). MAX [43] demonstrates that lock contentions are the major reasons for poor scalability in file systems. These works exploit the potentials of parallelism on multicore processors and fast SSDs through localized key data structures and fine-grained lock designs. The Linux kernel contributors optimize lock mechanisms to improve read performance [52]. In this paper, StRAID focuses on optimizing the write path of the MD parity-RAID architecture and addresses the software overhead in handling stripe writes.

7 Conclusion

We experimentally reveal that Linux MD with parity-based RAID systems cannot fully exploit the potentials offered by high-performance SSDs due to the architectural drawback of centralized stripe-writes. We propose a stripe-threaded parity-RAID (StRAID) to efficiently handle stripe-writes in parallel. StRAID introduces a two-phase stripe submission mechanism for aggregating partial-stripe writes and a parity cache for hot parity-accesses. Through extensive trace-driven evaluations, StRAID is shown to significantly and consistently outperform MD parity-based RAID in write performance without sacrificing read performance.

VINTER: Automatic Non-Volatile Memory Crash Consistency Testing for Full Systems

Samuel Kalbfleisch

Lukas Werling
Karlsruhe Institute of Technology

Frank Bellosa
Karlsruhe Institute of Technology

Abstract

Non-volatile memory (NVM) is a new byte-addressable storage technology that is part of the processor’s memory hierarchy. NVM is often exposed to applications via an in-kernel file system. To prevent data loss in the case of crashes, the file system implementation needs to be crash-consistent. Achieving crash consistency is difficult however, as special primitives need to be inserted at appropriate places in the program to ensure persistency in the presence of volatile caches.

We introduce VINTER, a new approach to automated NVM crash consistency testing designed for full systems, including unmodified kernel software such as file systems. By tracing NVM accesses of a full system via dynamic binary translation, we capture interactions between user and kernel space code. With such traces, our system efficiently generates relevant crash states using a heuristic that determines NVM locations significant for crash consistency. Finally, it extracts the semantic representation of each crash state. This makes the automatic detection of operation-spanning violations of crash consistency properties such as atomicity feasible. Our approach further aids in fixing detected bugs by representing how bugs originate from simulated crashes which are annotated by trace metadata.

Our evaluation on NVM file systems uncovers several previously unknown bugs, including bugs in the state-of-the-art file systems NOVA and NOVA-Fortis that lead to atomicity violations and data loss.

1 Introduction

Non-volatile memory (NVM) is a new storage technology that is byte-addressable and integrated in the processor’s memory system. Applications can obtain a virtual memory mapping to access non-volatile memory pages directly with load and store instructions [40, 41, 52]. Such direct access enables persistency without a serialization step, but requires extensive reworking of the applications to ensure crash consistency: Modifications need to be flushed from volatile caches, and

developers need to employ memory fences to enforce persistency ordering. Thus, programming for NVM has turned out to be difficult in practice [39].

As an alternative, unmodified applications can benefit from high-speed NVM by running on NVM file systems [5, 23, 26, 45, 48–51, 54, 56] which implement common user space interfaces such as POSIX [15]. Internally, these file systems store metadata and file data directly on NVM, which means that the same challenges for achieving crash consistency apply to these file systems as well.

Recent research has produced many approaches to detecting crash consistency bugs [8, 11, 27–30, 33]. However, we find that most of these approaches cannot easily be applied to file systems. Kernel software is often not supported at all or requires extensive code modification. In particular, static code analysis [11] and symbolic execution [33] are difficult to apply to full systems where a variety of user and kernel space code may interact. It is possible in theory to adapt a kernel file system to user space in order to apply a testing tool designed for user space software. However, this approach is likely to distort results, as the interaction between user and kernel space code can be a source of consistency bugs. For example, the NOVA file system [49] relies on memory barriers being performed when returning to user space.

We introduce VINTER, the virtualization-based NVM tester, a novel approach for testing crash consistency that supports full systems. Using binary translation, we trace relevant instructions such as load-store instructions or barriers in a virtual machine running unmodified kernel and user space code. From that trace, we generate *crash images* which represent possible NVM contents after a crash. We reduce the exponential search space by identifying NVM locations where the recovery code reads from the crash image. By extracting the *semantic state* of each crash image (e.g., a listing of all files in a file system), we can finally automatically verify crash consistency properties such as atomicity.

We use our prototype to test the NVM file systems NOVA [49], NOVA-Fortis [50] and PMFS [10] for crash consistency bugs. We find several new bugs in these file systems

ranging from atomicity violations to data loss and broken file system states. One specific bug we find in NOVA highlights the importance of testing unmodified software instead of higher-level methods such as manual code annotation: A generic Linux helper function for an uncached memory copy has an optimized assembly implementation for x86 that leaves unaligned data in the cache. NOVA uses this function to copy file data to NVM and is thus susceptible to data loss.

We identify the following major contributions of our work:

- Our solution traces NVM accesses using full system emulation with dynamic binary translation. It thus supports unmodified user and kernel space software.
- We apply heuristics to achieve efficient exploration of crash states, avoiding combinatorial state explosion.
- Through grouping simulated crashes by their semantic state, we introduce *automatic* testing of operation-spanning crash consistency properties such as atomicity.
- To help developers fix uncovered bugs, we introduce a representation of semantic crash states and their origins in simulated crashes which are annotated by trace metadata.
- Using our solution, we provide the first comprehensive analysis of NVM file systems for crash consistency.

2 Background and Related Work

In this section, we introduce the memory persistency model that VINTER builds upon and the crash consistency properties it can verify automatically. Then, we discuss related work.

2.1 Memory Persistency Models

Applications that access NVM need to pay close attention to the *memory persistency model* which codifies the architecture’s guarantees about persistency. Multiple models have been proposed [5, 12, 18, 35]. We implement VINTER for the x86 architecture [17, 37] whose persistency model is based on *persistency epochs* [20]. The epoch model divides thread execution into persist epochs and guarantees that stores between epochs are strictly ordered, but not within the same epoch [5, 35]. Stores are buffered in x86 and need to be flushed from volatile caches with instructions such as `clwb` to be persisted [22, 37]. Alternatively, *non-temporal stores* bypass the caches. Memory barriers in the form of `fence` instructions provide *ordering points* that divide the epochs. In the following, we refer to all instructions that are relevant for the persistency model as *persistency primitives*.

2.2 NVM Crash Consistency

Crash consistency as a property of stateful applications is often only informally specified. Throughout this work, we use the following definitions and assumptions about the tested applications.

Figure 1: An atomic operation: All crash images (partially shown) recover to one of two semantic states.

We assume that the application keeps its persistent state in NVM. Depending on the access method, modifications may go through a volatile cache or may be reordered. After a crash, these modifications may be partially lost. Consequently, the NVM then contains all fully-persisted data (e.g., through cache flush instructions and memory fences) with a subset of the in-flight modifications applied. We call this a *crash image*.

The period during which a crash may occur is called the *pre-failure* execution [29]. When restarting the application from a crash image, its *post-failure recovery* code will read the data to recover its semantic state. By comparing all possible recovered states that can arise from crashes, we can describe the following crash consistency properties. An operation with all-or-nothing semantics fulfills *atomicity*. More formally, all crash images possible during an atomic operation result in one of two states: either the initial or the final state. Figure 1 illustrates such an atomic operation. From left to right, an application is modifying NVM contents step-by-step. As long as the modifications are not flushed from the caches, crash images with partial cache contents are possible. However, all but the final crash image recover to an identical semantic state. We can observe patterns like this when techniques such as journaling are in use. The final writes (green) mark the previous modifications as valid.

For non-atomic operations, in Section 3.4.1 we define a second, weaker property *Single Final State*: at the end of an operation, all possible crash images recover to the same semantic state. Either of these properties may be violated by different kinds of bugs. For example, a missing memory fence at the end of an operation may violate Single Final State: the CPU could reorder cache flushes, which results in crash images that miss some modifications.

Multiple methods exist that help applications to achieve crash consistency, including logging [46, 47], log structuring [4, 14, 24, 49, 55], and shadow paging [31, 34].

2.3 NVM Crash Consistency Testing

Since making NVM programs crash-consistent is difficult for developers, multiple testing approaches have been proposed

with varying degrees of automation. Many of the previous approaches rely on user-provided code annotations [29, 30], do not automatically confirm bug candidates [8, 29, 30, 33], and are limited to user space applications [11, 29, 33] or would need additional effort like kernel modification [8, 28, 30]. VINTER is free from these limitations.

Lantz et al.'s Yat [27] traces its target in a hardware-assisted hypervisor, constructs all possible crash images by brute force, and tests these by running an integrity checker such as `fscck`. It is able to test kernel space applications, but it relies on code modifications to trap persistency primitives due to limits of hardware-assisted virtualization. Due to its exhaustive crash image exploration, some test cases would take years to complete. Furthermore, Yat can only detect inconsistencies discovered by an integrity checker, and is not able to consider consistency across entire operations.

Liu et al.'s PMTest [30] requires that developers annotate their source code with persistency assertions. Their correctness is then evaluated at runtime. The obvious drawback is that the approach entirely depends on the quantity and quality of annotations which need considerable effort by developers.

XFDetector by Liu et al. [29] applies heuristics to detect a typical bug pattern. During runtime, it looks for read operations during post-failure recovery whose corresponding stores from pre-failure execution have not been explicitly persisted. To avoid false positive bugs, they require manual code annotations. Still, the bug candidates need manual screening.

Neal et al.'s Agamoto [33] applies symbolic execution to NVM user space programs. This allows arguing over many possible execution paths at once and can work with symbolic NVM. It only detects some bug patterns like unpersisted NVM locations after program termination. Thus, false positives can occur and manual vetting is required.

WITCHER by Fu et al. [11] focuses on testing user space key-value stores. The authors propose a testing pipeline that automatically confirms bugs. It uses heuristics based on dynamic and static analysis to choose interesting crash states and thus avoids exhaustive search. Use of static analysis and need for recompilation makes it difficult to apply to full systems, so we propose a new crash image generation heuristic solely based on dynamic analysis. WITCHER automatically detects violations of the *atomicity* of operations [18] by introducing “output equivalence checking” that compares with oracle states obtained before and after an operation. Our work extends upon this by also testing for a relaxation of atomicity. Furthermore, VINTER outputs a representation of all encountered semantic crash states for easy manual sighting when strong properties such as atomicity do not apply. VINTER also passes metadata through its testing pipeline in order to facilitate debugging and root cause analysis of uncovered bugs.

PMFuzz by Liu et al. [28] uses fuzzing for test case generation and is orthogonal to our work. PMDebugger by Di et al. [8] focuses on efficiently processing memory traces.

Formal verification of NVM programs has been proposed [7, 13, 18].

2.4 File System Crash Consistency

The need for file systems to tolerate crashes is not new. Numerous works have proposed methods for checking crash consistency properties in file systems [19, 21, 25, 32, 36, 53]. Most of these approaches rely on instrumentation at the block layer and thus cannot be applied to NVM file systems. However, we see opportunities to adopt specific techniques to an NVM context. CrashMonkey [32] automatically generates test cases for a crash consistency checker. Our evaluation relies on manually written tests, but could be extended with a similar technique. Jaffer et al. [19] evaluate how file systems react to media errors common on solid state drives. Our approach could be extended in this direction, however, there is currently limited information on specific NVM media errors.

File system semantics. A common issue with file system crash consistency checking is that consistency semantics vary from file system to file system and are often only loosely specified. The POSIX standard [15], whose API most Unix file systems implement, does not define crash consistency semantics at all. Bornholt et al. [3] improve on this situation by creating crash consistency models for a few commonly used file systems. Rebello et al. [38] specifically look at error handling by file systems and applications for the `fsync` system call. These issues also apply to NVM file systems. For our analysis, NOVA [49], NOVA-Fortis [50] and PMFS [10] give strong atomicity guarantees for all metadata and file data operations, so complex models were not required.

3 Approach

We introduce a novel crash consistency testing approach to automatically finding bugs that violate crash consistency properties in unmodified NVM applications, including kernel space software. The key requirements for our solution are:

- To support kernel software such as file systems, it should work with *full systems* and should not be limited to user space software.
- It should not require manual development effort. In particular, no code annotations should be needed. Our solution even works with *unmodified* kernel and user space binaries without needing source code access.
- Reported crash consistency bugs should be *automatically confirmed*, and not be based on heuristics that allow for false positives.
- For good performance, it should *avoid exhaustive search* over all possible crash states, and only consider crash states that are likely to exhibit crash consistency bugs.
- It should not only look for single crash states that are obviously broken, but also consider *semantic, operation-spanning crash consistency* such as atomicity. For ex-

Figure 2: Overview of the testing pipeline. Components are in boxes; arrows are labeled with inputs or produced artifacts.

ample, this allows to determine whether a file system operation is atomic or has invalid intermediate crash states.

3.1 Overview

VINTER dynamically analyzes the execution of a system that interacts with NVM. The goal is to simulate crashes that may occur during a recorded pre-failure execution and find inconsistent states. The proposed framework consists of a testing pipeline made up of multiple components which we depict in Figure 2.

The pipeline’s initial input is an operating system image, which includes all kernel and user space binaries, as well as a sequence of operations that specifies the program’s pre-failure execution during which crashes should be simulated. Each step of the pipeline outputs an artifact that is fed to the next stage of the pipeline. In the final step, uncovered crash consistency bugs and a representation of encountered semantic crash states are output. The entire pipeline may be run multiple times with different test cases. Achieving comprehensive results depends on the quality and quantity of these cases being run in the system. Finding these is orthogonal to our work (e.g., PMFuzz [28]).

VINTER’s *Tracer* makes use of full system emulation with dynamic binary translation to trace NVM operations performed by a system (§3.2). The resulting trace is fed into our *Crash Image Generator*. To be able to reconstruct arbitrary crash states, the Crash Image Generator uses an *NVM simulation* of a given memory persistency model to replay the trace on it (§3.3). At each ordering point (e.g., memory barrier), crash images are chosen by a heuristic that only considers in-flight stores at memory locations likely to be read by the recovery (*post-failure*) code, which avoids exhaustive exploration of crash states. The latter are determined by running the post-failure code on special crash images, hence the Crash Image Generator uses its own Tracer instance.

The *Tester* component finally takes crash images and extracts their *semantic (crash) states* (§3.4). Each of the pre-failure operations is then analyzed for violations of crash consistency properties such as atomicity. For example, if during an operation three different semantic crash states are observed,

the operation has been shown not to be atomic. Uncovered bugs are finally output to the user of the framework, together with a representation of encountered semantic crash states and how they originate from the simulated crashes (§3.5).

The workflow of our testing pipeline is similar to the one in the WITCHER framework proposed by Fu et al. [11]. However, our crash image generation algorithm additionally makes use of the Tracer as part of our heuristic for choosing crash images (we further compare our solution in §2.3).

3.2 Tracer

The Tracer is a full system emulator and is used in the testing pipeline for the following purposes:

- During pre-failure execution, we trace *writes* to NVM as well as invocation of *persistency primitives*, as this allows reconstruction of arbitrary NVM crash states (§3.3).
- Further, we trace *reads* to NVM during post-failure executions as part of our crash image generation heuristic described in Section 3.3.
- Optionally, the Tracer may be used by the Tester component for running the post-failure recovery on the generated crash images to extract their semantic states (§3.4). Tracing NVM accesses may be disabled, but hypercalls can be used (see below).

In common architectures, NVM is accessed directly via load and store instructions to virtual memory that is backed by NVM. Further, persistency primitives (such as cache line flushes and memory fences) are usually implemented as dedicated instructions. To intercept these events, we base the Tracer’s processor emulation on *dynamic binary translation* [43]. This allows full control over the emulated system, and is transparent to the tested program stack, thus binaries may remain unmodified. In contrast, hardware-assisted virtualization (as used by Yat [27]) is faster, but does usually not provide hooks for all events that are of interest (Yat requires recompilation).

During the translation of basic blocks from the emulated architecture to the host architecture, the Tracer adds instrumentation code for persistency primitives to the translated code. Further, the memory abstraction layer of the emulator intercepts memory writes and reads to address ranges backed by simulated NVM. The intercepted events are then output in a *trace log* with associated data. Data includes instruction operands (e.g., cache flush addresses) or memory contents updated by a store to NVM.

Hypercalls. We allow the emulated system to signal the following events as hypercalls to the testing framework, which are additionally recorded in the trace log:

- *Checkpoint* hypercalls during pre-failure execution separate semantic operations. We remind that input to the testing framework is a sequence of operations that will each be separately tested for operation-spanning crash consistency. In practice, this may be in form of a sim-

ple user space executable that calls the tested program's operations and emits hypercalls in between.

- *Success indication* hypercalls may occur during post-failure recovery. If none is emitted, it is assumed that recovery from the specific crash image has failed.

The use of hypercalls is not mandatory for the approach, but it improves the testing workflow for example by allowing separation of operations during pre-failure execution.

Metadata. During pre-failure execution, we log metadata about traced events (such as NVM stores), particularly their location in form of a call stack as traced by the emulator. Although not required to detect crash consistency bugs, it helps a developer to investigate uncovered crash consistency bugs. We retain this metadata when generating crash images later in the pipeline as a way to understand how a crash needs to occur to lead to a certain invalid semantic crash state. Further, additional events helpful for debugging may be traced and logged, such as system calls.

3.3 Crash Image Generator

The Crash Image Generator component takes a pre-failure trace as its input, and it outputs crash images to be passed into the Tester (§3.4). A crash image is a string that describes the binary contents of the NVM in a single crash state that can occur according to the memory persistency model at an arbitrary point of program execution.

Motivation and challenges. In memory persistency models that are based on persistency epochs [5, 35] (including x86 [20]), the set of all possible crash images can be constructed as follows. At each ordering point (usually memory fences), apply any possible subset of potentially unpersisted in-flight stores on top of the memory contents that are already guaranteed to be persisted [8, 11, 27–30, 33]. This works because stores can only become irreversibly persistent at ordering points. Not all subsets may be allowed and order of stores can be relevant depending on the specific memory model [35, 37, 42], such as x86 with intra-cache-line ordering.

Although considering any possible crash state would be comprehensive, it is impractical. Yat by Lantz et al. [27] does so, but the authors find that some test cases would take several years to complete due to exponential explosion in number of crash images. Thus, many other approaches do not actually generate and test crash images, but only apply heuristics on the observed program execution to detect typical bug patterns [8, 29, 30, 33]—this either allows false positives to occur or requires extensive manual code annotations.

Solving this problem requires reducing the number of tested crash images. The chosen subset of crash images should ideally not hide bugs. Accordingly, the chosen crash images should have some properties that makes them relatively likely to exhibit bugs. The recent WITCHER framework proposed by Fu et al. [11] aims to solve this challenge for user space key-value stores: From a mix of static and dynamic analysis, they

infer *likely invariants* regarding the persistency of program data that have presumably been intended by the programmer. Then, they choose crash images that violate these invariants and test if these indeed violate crash consistency. This approach works well for key-value stores, but particularly the reliance on static analysis makes it difficult to apply to full systems, where a variety of user and kernel space code may interact.

Proposed crash image generation heuristic. In contrast, our heuristic only relies on dynamic analysis. For determining crash consistency, only the semantic state as recovered by the application in post-failure recovery is relevant (§3.4). Conversely, the semantic crash state can only have been influenced by *memory locations from which the post-failure execution has read*. Our crash image generation heuristic is based on this idea. When choosing subsets of in-flight stores during crash image generation, our heuristic only considers stores likely to be read by the post-failure recovery. Other stores may be ignored.

We observe that techniques such as journaling and log structuring, both common in file systems, cause the following access pattern: The program writes a journal entry, flushes it completely to NVM and only marks it valid after a store fence. The journal entry may have an arbitrary size, resulting in a large number of in-flight stores. However, considering subsets of these stores for crash image generation is not useful. After a failure, the recovery would only read a journal entry that is marked valid.

According to this observation, we base the decision on whether a store is likely to be read in post-failure recovery on the following assumption: If an NVM location is not read during the post-failure stage on the image where all unpersisted stores are applied, the post-failure stage will likely also not read this location when an arbitrary subset of in-flight stores is applied. Therefore, the heuristic limits the generated crash images to variations of stores that *are* likely to be read during the post-failure stage's execution. As with any heuristic, the assumption may not always hold. We evaluate its effectiveness in Section 6.2.

For the heuristic to capture all relevant NVM locations, the post-failure recovery should read all relevant state, for example by running code that serializes all state (as in the state extractor to be introduced in Section 3.4).

The heuristic's underlying idea of observing interactions between pre- and post-failure executions is based on Liu et al.'s XFDetector framework [29]. However, XFDetector uses these observations directly to detect bug patterns, but does not automatically confirm bug candidates. It further requires developers to manually annotate their code to mark memory belonging to commit variables; it is further not directly compatible with checksumming mechanisms as used by file systems.

NVM simulation. To be able to replay the trace and reconstruct the possible NVM crash states, we assume a simu-

lator of the architecture’s memory persistency model. It holds the *guaranteed persisted memory* content as a binary string, and further a list of *in-flight stores* that have not yet been explicitly persisted. Each of these stores further retains associated metadata from the trace. It further needs to provide functions for applying stores and persistency primitives (e.g., cache line flushes and ordering points). An efficient data structure and algorithm for processing in-flight stores have been proposed by Di et al. [8].

Resulting algorithm. The algorithm processes the pre-failure trace from beginning to end and replays each NVM write operation and persistency primitive invocation on the NVM simulation. At each ordering point, it generates crash images in the following way:

1. Obtain a copy of the current NVM’s guaranteed persisted memory, and apply all stores on it. We obtain NVM_{full} .
2. Instantiate the Tracer with NVM_{full} as initial NVM contents. Execute and trace the post-failure recovery.
3. Look for “read” operations in that post-failure trace to NVM addresses that have overlapping in-flight stores.
4. Consider all subsets of these cross-failure read in-flight stores, and apply each subset to the guaranteed persisted memory and emit the resulting crash images.
5. Continue with replaying the pre-failure trace.

As an optimization, we ignore ordering points if no stores to NVM have occurred before the last one. Further, if there would be too many subsets of cross-failure read in-flight stores according to a configurable threshold, we choose a random selection of these subsets.

Metadata. It is possible for the same crash image (merely a binary string) to be emitted multiple times, but at different ordering points and with different subsets of stores applied. We deduplicate crash images and attach metadata to each image that describes all its *origins*. Each origin includes the (un)persisted in-flight stores’ metadata (containing the stack trace that led to a store), the last ordering point’s ID, and the last checkpoint’s ID. Crash images are further grouped by checkpoint (i.e., the semantic operation they occur during).

3.4 Tester

In the previous step of VINTER’s testing pipeline, we have generated crash images that simulate crashes at multiple points during the traced pre-failure program execution. In this final step, the Tester component analyzes each operation’s crash images for the occurrence of crash consistency bugs. We begin by defining crash consistency properties (§3.4.1) and then describe how the Tester component discovers violations of the properties from a set of crash images (§3.4.2). Our testing approach is an extension of Fu et al.’s “output equivalence checking” [11].

3.4.1 Crash Consistency Definitions

The central idea is that an NVM image can be mapped to an application-specific well-defined *semantic state* that describes the intended meaning of the persisted data. The same semantic state can possibly be encoded by different NVM images. We use \mathcal{S} to describe the set of semantic states, and \perp ($\perp \notin \mathcal{S}$) to denote that an NVM image is not recoverable from because it is faulty. The *state extractor* function E maps NVM images to semantic states, for which we use the notation $E : \{0, 1\}^* \rightarrow \mathcal{S} \cup \{\perp\}$.

We recall that we allow traces to be separated by *checkpoints* (c_1, c_2, \dots) that are signaled by the running program through hypercalls (§3.2). We define *checkpoint intervals* $[c_i, c_{i+1}]$ —called *operations* in the following—that each induce a subsequence of a trace that contains all its recorded events between checkpoints c_i and c_{i+1} . We use checkpoints to separate different semantic operations during the pre-failure execution traced in the beginning of our testing pipeline. We define two crash consistency properties which, depending on the operation, may be considered a requirement for crash consistency of the operation.

We propose the following new property:

Definition 1 (Single Final State, SFS). A checkpoint c_k is single-final-state crash-consistent ($SFS(c_k)$) if and only if all crash images $N_k \subset \{0, 1\}^*$ that can result from crashes in the trace exactly at checkpoint c_k result in the same state $\neq \perp$, or formally: $\exists s \in \mathcal{S} : \{E(n) \mid n \in N_k\} = \{s\}$.

For $s \in \mathcal{S}$, we write $SFS(c_k, s)$ if c_k is single-final-state crash-consistent and $\{E(n) \mid n \in N_k\} = \{s\}$. Further, an *operation* $[c_i, c_{i+1}]$ is single-final-state crash-consistent if and only if c_{i+1} is single-final-state crash-consistent.

SFS is a property that is useful to require even when an operation is not considered atomic; in that case, intermediate states are allowed, but as soon as an operation returns, a crash may not yield any intermediate states anymore.

We further define the well-known atomicity property in our context:

Definition 2 (Atomicity). An operation $[c_i, c_{i+1}]$ is atomic if and only if c_i and c_{i+1} are both single-final-state crash-consistent, and all crash images $N_{[i, i+1]} \subset \{0, 1\}^*$ that can result from crashes anywhere between checkpoints c_i and c_{i+1} result in either of two states $\neq \perp$, or formally:

$$\exists s_{\text{before}}, s_{\text{after}} \in \mathcal{S} : SFS(c_i, s_{\text{before}}) \wedge SFS(c_{i+1}, s_{\text{after}}) \\ \wedge \{E(n) \mid n \in N_{[i, i+1]}\} = \{s_{\text{before}}, s_{\text{after}}\}.$$

Atomicity means that operations execute, from the point of view after crash recovery, in an all-or-nothing fashion: Either an operation is fully run (s_{after}) or not at all (s_{before}). No intermediate states should occur and all states should be recoverable. This means that no more than two states may be observable after recovering from arbitrary crashes between

Figure 3: Representation of an operation’s semantic states and their origins’ metadata as output by VINTER.

the two checkpoints of an operation. An atomic operation is obviously also SFS crash-consistent, but SFS crash-consistent operations exist that are not atomic.

The state extractor E will usually be implemented by running the application’s post-failure recovery on the given crash image including a step that serializes the state. Additional tests may be run after the recovery to ensure correctness (such as `fsck` on file systems). In this case, if a hypercall indicating success is not issued by the post-failure recovery, the state is mapped to \perp . The Tracer component can be reused to provide a virtual environment that implements these hypercalls.

3.4.2 Testing Crash Consistency Properties

VINTER’s Tester component finds crash consistency violations given a set of crash images from the previous step of the testing pipeline. As its input, we assume a map of (already deduplicated) crash images to lists of the metadata that describe an image’s (possibly multiple) origins (§3.3).

The Tester builds a table $M_{cp \rightarrow states}$ that maps checkpoint IDs to semantic states which originated from crash images where the most recent checkpoint hypercall had the corresponding ID. As an image can have multiple origins with different checkpoint IDs, a semantic state may be mapped to more than one checkpoint. It also builds another similar table $M_{cp \rightarrow fin. states}$, with the exception that only images are considered that result from crashing directly at a checkpoint boundary, thus only considering the “final” states at the end of an operation.

It is easy to find violations of crash consistency properties by scanning the tables:

- The *Single Final State* property of a checkpoint is valid if and only if $M_{cp \rightarrow fin. states}$ contains exactly one state for that checkpoint.
- The *Atomicity* property of an operation $[c_i, c_{i+1}]$ is valid if and only if c_i and c_{i+1} are SFS crash-consistent (with $M_{cp \rightarrow fin. states}[c_i] = \{s_{before}\}$ and $M_{cp \rightarrow fin. states}[c_{i+1}] = \{s_{after}\}$) and $M_{cp \rightarrow states}[c_i] = \{s_{before}, s_{after}\}$.

Violations of these properties are reported by the Tester.

Further, for each operation it outputs a representation of all encountered semantic crash states with their associated crash images and the crash images’ origins (Figure 3). This representation helps with root cause identification as we cover in the following section.

3.5 Bug Analysis

The Tester’s output lets developers determine whether crash consistency bugs have been uncovered. Trivially, if the extracted semantic states include an unrecoverable state (\perp), a bug has been uncovered. Otherwise, in the simple case, a developer specifies that a certain operation should hold one of the previously covered crash consistency properties, and then a violation reported by the Tester implies a bug. However, the crash consistency semantics of an operation may be more complex or even unclear and may allow multiple intermediate states. The developer can then manually inspect the encountered semantic states for their validity (as output in the maps $M_{cp \rightarrow states}$ and $M_{cp \rightarrow fin. states}$). Alternatively, they can automate the decision by implementing an operation-specific predicate that validates whether for a set of semantic states the operation is crash-consistent.

Once bugs have been discovered, VINTER aids developers in understanding their root causes by representing how crash-consistency-violating semantic states originate from simulated crashes. As depicted in Figure 3, every semantic state keeps a link back to the crash images it was extracted from, and each crash image keeps a link to the simulated crashes’ states (origins) it was created from. As a crash image only represents the NVM’s binary contents, multiple different crash images may lead to the same semantic state (e.g., an uncommitted journal entry does not contribute to the semantic state). Further, crashing at different ordering points or with different subsets of in-flight stores applied, as stored in the “origin metadata,” may lead to the same crash image.

Each crash image origin includes a list of in-flight stores at the ordering point (fence) where the crash was simulated, as well as the subset of in-flight stores applied to obtain the crash image. Each of the ordering points and their in-flight stores is annotated with its stack trace (as logged by the Tracer) and thus maps back to its source code location.

By inspecting the origins of a crash-consistency-violating semantic state, developers can understand where and how a crash needs to occur to trigger the bug (as in source code location and persistency status of NVM data). This eases root cause identification. For example, if *all* of an invalid state’s origins have a *strict subset* of in-flight stores applied (i.e., the crash image at the same ordering point with all in-flight stores applied does not lead to the invalid state), then introducing more persistency ordering constraints (fences) may likely fix the bug.

We present two concrete bug analyses in Section 5.3.

4 Implementation

We implement a prototype of VINTER for the 64-bit x86 architecture [17]. Its tracer is based on PANDA [9] and Py-PANDA [6], which provide a platform for dynamic analysis built on QEMU [1]. QEMU is a full system emulator based on dynamic binary translation. Core parts of our prototype are written in Python. Therefore, while its performance is sufficient for our file system evaluation, considerable improvements are likely possible without changing the general approach. VINTER’s prototype is available and described in [Appendix A](#).

Our NVM simulator implements x86’s memory persistency model [17, 37]. By dividing the simulated NVM into segments of 64 bytes and keeping ordering of in-flight stores within these lines, VINTER respects intra-cache-line ordering constraints. This guarantees ordering even of non-temporal stores, which is a higher guarantee than the architecture gives. Setting the segment size to 8 bytes would allow testing reordering of non-temporal stores, but would also break intra-cache-line ordering which some NVM file systems rely on [10].

5 File System Crash Consistency

The crash consistency testing tool we have described so far does not have any parts specific to file systems and could be applied to arbitrary software running in a virtual machine. In this section, we describe how to apply it to NVM file systems. Then, we present the results of our analysis of NOVA [49], NOVA-Fortis [50] and PMFS [10].

Our testing pipeline requires an application-specific *state extraction procedure* for mapping from a crash image to its semantic state. The Tester component boots a virtual machine with the crash image, runs the procedure, and records the output or a failure state \perp in case of errors. We implement file system state extraction as follows:

1. Mount the file system read-only.
2. Traverse the file system and output a serialized representation of each file.

We need to mount the file system read-only to prevent inadvertent changes to metadata such as file access timestamps. The file systems we target adhere to the POSIX standard [15], which allows us to build a generic state extractor for all POSIX-compatible file systems. For each file (including regular files, directories, symbolic links) we output a serialization of its path, its contents, its type, and most metadata from the *stat* structure¹.

After the state extraction completes, we verify that the file system can still be modified. We remount the file system as writable and run an additional test-case-specific command that modifies some of the files or directories used in the test.

¹We exclude runtime properties such as device IDs and preferred I/O block size.

If any of these operations fail, we mark the state described by this crash image as failure state \perp .

Our notion of consistency only encompasses the file system state as visible via the file system API. The underlying assumption is that if the file system is still properly readable and writable, its state can be considered consistent without the need to inspect its internal state.

For testing more traditional file systems that depend on separate integrity checkers (`fsck`), these could also be run as part of the state extraction procedure and map to the failure state \perp if the integrity checker fails.

5.1 File System Setup

For each tested file system, we need a corresponding virtual machine image. To reduce the time required for tracing, we hand-craft minimal VM images consisting of a statically-linked Linux kernel image with a user space based on Busy-Box [44]. We do not use an init system. Instead, we let the system spawn a shell that accepts test commands over a virtual serial console. Consequently, there are no unrelated processes running in the background during tracing.

5.2 Test Cases and Results

We manually craft 16 test cases consisting of operation sequences which cover most basic file system operations. [Figure 4](#) shows a summary of the test cases and the results. Most test cases correspond to basic file system operations given in monospace font. The “atime” and “[cm]time” test cases update the corresponding timestamps as side effects of a file read or directory operations², whereas “touch” uses a system call for that purpose. We test three variants of the `rename` operation: a rename that overwrites an existing file (`overwrite`), moving a directory into another (`directory`), and changing the file name to a longer one (`long name`). The “long name” test case creates a file with a long file name and writes to it. Test cases with “long” file names use a name that exceeds the cache line size (which is 64 bytes). Finally, “update” modifies a small part in the middle of a larger file.

In total, VINTER finds previously unreported bugs in 7 out of 16 test cases for NOVA. We analyze these bugs manually and find three root causes. First, we observe missing cache flushes when NOVA writes unaligned data to NVM which lead to data loss. This issue manifests in our test cases “write” and “symlink,” but could also occur in “append” and “update” (marked with an asterisk) depending on the length of the written data. The test cases with long filenames (i.e., longer than cache line size) suffer from the same issue and result in files where reading the metadata with `stat` fails. Second, the rename operation is not atomic. We observe crash states where the renamed file or directory is completely missing.

²Adding or removing files from a directory updates the directory’s change and modification timestamps.

❤️ data loss 🚫 crash 🚫 atomicity violation 👁️ read/write fails after recovery 🍷 multiple final states (SFS violation)

Figure 4: Crash consistency bugs discovered by VINTER.

In the following section, we give a detailed analysis of these two bugs. Third, creating hard links is not completely atomic. Our tool detects a crash state where the original file’s link count (`st_nlink`) is incremented, but the new link does not yet exist.

As NOVA-Fortis is an extension of NOVA with the addition of checksumming and parity, it shares most of the issues we find in NOVA. However, we see three additional failing test cases. Our tool discovers intermediate crash states where both data and the checksum over that data are only partially persisted. This leads to checksum errors during recovery and errors when trying to read or write the affected files. We also observe an instance where the additional data integrity mechanisms help: In the “write” test, NOVA-Fortis does not suffer from data loss since it can recover the unpersisted data from parity. However, it appears that NOVA-Fortis does not protect all data that way: The data loss in the “symlink” test case shares the same root cause as for “write,” but still occurs in NOVA-Fortis.

PMFS suffers from fewer failing test cases than the NOVA variants. We observe a minor atomicity violation in test cases that remove or overwrite a file. Before the file disappears, crash states exist where the file has updated change and modification timestamps. A more serious issue can occur when removing files in the root directory: Crash states are possible where mounting the file system results in a failing assertion, which leads to a crash of the PMFS kernel module.

We reported all NOVA and NOVA-Fortis bugs to the developers³. We did not report PMFS issues since it is not maintained anymore.

5.3 Analysis

VINTER has discovered several previously unreported crash consistency bugs in the NOVA variants. In the following, we exemplarily provide a detailed analysis of two of these bugs that highlights advantages of our crash consistency testing

³Issue IDs 105, 116, 121–125; each accessible at <https://github.com/NVSL/linux-nova/issues/<ID>> (also on archive.org)

| unpersisted stores | call stack of store (metadata) |
|--------------------|---|
| 0x2db008 ↦ 1 | ↳ <code>__copy_user_nocache</code> |
| 0x2db009 ↦ d | ↳ <code>do_nova_inplace_file_write</code> |
| | ↳ ... |
| 0x2db00a ↦ ↓ | ↳ <code>vfs_write</code> |
| | ↳ ... |

Figure 5: The unpersisted stores after writing `HelloWorld↓` to a file in NOVA. The bytes 1, d, ↓ are the last three bytes of the string.

| event | operand | instr. (metadata) |
|------------|--|-------------------------------------|
| syscall | <code>sys_write(fd=1, buf='HelloWorld\n', n=11)</code> | |
| ... | ... | ... |
| write (NT) | <code>0x...0 ↦ HelloWor</code> | <code>movnti qword [rdi], r8</code> |
| write (T) | <code>0x...8 ↦ 1</code> | <code>mov byte [rdi], al</code> |
| write (T) | <code>0x...9 ↦ d</code> | <code>mov byte [rdi], al</code> |
| write (T) | <code>0x...a ↦ ↓</code> | <code>mov byte [rdi], al</code> |
| fence | | <code>sfence (store fence)</code> |

Figure 6: Excerpt of the trace that shows how the file contents are written to NVM. No flush operations follow on the cache line belonging to the temporal stores.

approach. Furthermore, the analysis illustrates how VINTER helps manual analysis with the metadata carried throughout the testing pipeline and presented as part of the Tester’s report.

5.3.1 Incompletely Persisted Data

We first analyze the data loss bug occurring in the test case “write” (see Figure 4). The test case creates a file and writes the string `HelloWorld↓`, as in the shell command `echo HelloWorld > /mnt/myfile`. Our tool detects a violation of Single Final State and records partially persisted file contents where up to three bytes at the end are replaced with zero (e.g., `HelloWor000` and `HelloWorl000`).

First, we take a look at the unpersisted stores as reported

Figure 7: Observed crash states in NOVA during a rename of file *a* to *b* in a directory, intending to replace *b*. Boxes represent files. (1) is the initial state.

by the Tester component. As pictured in Figure 5, each store is associated with a call stack. We see that the stores originate from a `write` system call and that NOVA uses the function `__copy_user_nocache` to write to NVM.

Next, we inspect the NVM trace pictured in Figure 6. It captures the system call entry as well as all writes to NVM, cache flushes, and memory fences. Non-temporal writes (NT) are distinguished from temporal writes (T) as the former bypass the volatile caches. We see that the helper function `__copy_user_nocache` writes the first eight bytes of the string to NVM with a single non-temporal store, then writes the remaining bytes one by one with temporal stores. As there is no cache flush operation, these bytes end up unpersisted.

Further investigation in the Linux source code shows that `__copy_user_nocache` has an architecture-specific implementation for x86 implemented in assembly. As the function was written with performance and not persistency in mind, the Linux developers deemed it acceptable to use temporal stores for unaligned data.

This bug highlights the importance of testing *unmodified* software. Using an approach that relies on source code annotations to trace NVM events, a developer would likely assume that the Linux helper function works correctly and would annotate it accordingly without following through to the architecture-specific assembly implementation.

5.3.2 Data Loss During Rename

Second, we analyze the atomicity issues of the `rename` operation in NOVA. As depicted in Figure 4, our tool detects atomicity violations and data loss for all variants we test (overwriting a file, renaming a directory, and a normal rename with long file names). We visualize the crash states for the overwrite variant in Figure 7. In addition to the initial state (1) and the desired final state (4), we observe a state where the file to be renamed is missing (2), as well as a state where the target file is also missing (3). For the other two test cases that do not overwrite files, we observe crash states similar to (2) where the file or directory is missing.

We find that both invalid crash states from Figure 7 have at least one crash image associated with an “origin” where all in-flight stores were persisted (i.e., includes all volatile cache lines; §3.5). Consequently, the bug does not stem from mistakes with NVM persistency primitives. We inspect the call

stacks for these crash images and find that they correspond to different locations in the `nova_rename` function. By inserting early `return` statements at these locations, we can reproduce the issue without our testing framework, thus confirming the issue.

This bug shows that our testing pipeline is also capable of finding persistency issues that are not specific to NVM. By carrying metadata such as stack traces through the pipeline, our framework makes bug verification easy.

6 Evaluation

In the previous section, we have shown that our approach is capable of finding new crash consistency bugs in file systems. We now give a more complete picture of our prototype’s performance by answering the following questions: Is the approach comprehensive or does it miss certain types of known crash consistency bugs? How effective is our crash image generation heuristic at reducing the search space of possible crash images? How big is the slowdown incurred by tracing and how fast are the other stages of the testing pipeline?

6.1 Completeness

It is well known that—outside of formal methods—software testing can only prove the existence of bugs, but not their absence. Nevertheless, we would like to evaluate the *completeness* of our approach: Does it miss certain types of real-world crash consistency bugs?

To this end, we sight all 45 issues and patches available on the public NOVA bug tracker which were submitted between 2019-01-01 and 2021-10-30. We include issues and patches that are related to crash consistency bugs. We exclude #110⁴ as according to the bug description, recovery from a crash only leads to error messages but no observed wrong behavior. We exclude #98, as according to the bug report, it requires an NVM capacity > 128GiB, which is infeasible with our evaluation setup. We are left with four different patches (#89, #92, #95, #109) that fix crash consistency bugs in NOVA and NOVA-Fortis.

To assess whether our prototype is able to find these bugs, we evaluate our prototype on a commit before and after each bug, and compare the Tester component’s reports. This way, we can ignore the crash consistency bugs we describe in Section 5 which may already be present in older NOVA versions.

Our prototype is able to find all of the known bugs chosen by our evaluation methodology. There is no need for special test cases. All bugs are triggered by at least one of the test cases we describe in Section 5.2.

⁴The numbers are IDs of issues or patches in the NOVA bug tracker and can be accessed at URLs of the following form: <https://github.com/NVSL/linux-nova/issues/<ID>> (also on archive.org)

| | $\mu \pm \sigma$ [s] |
|--|----------------------|
| total elapsed Tracer process time | 6.37 ± 0.11 |
| ↳ boot (only minimal instrumentation) | 1.63 ± 0.03 |
| ↳ trace (from outside) | 4.15 ± 0.10 |
| ↳ trace (in guest, portion of command) | 3.02 ± 0.05 |
| execution in guest with raw PANDA | 0.09 ± 0.00 |

Figure 8: Runtimes measured while tracing the pre-failure command of the “write” test case in NOVA. 20 runs, μ is mean and σ is sample standard deviation.

6.2 Effectiveness of Heuristic

We evaluate whether our proposed crash image generation heuristic based on cross-failure reads (§3.3) helps with efficiency as intended. To this end, we modify our prototype to consider *all* lines with unpersisted stores for crash image generation, rather than only lines overlapping with the unpersisted cross-failure reads as reported by our heuristic. We run this modified prototype on all NOVA test cases (§5.2).

We compare both the number of unique crash images generated (accumulated over all test cases), and the semantic crash states discovered by the modified prototype with that of the original prototype. 2466 unique crash images are produced by the modified prototype without the heuristic, versus only 438 crash images by the original prototype⁵. Thus, the prototype without the heuristic needs to test approximately 5.6 times as many crash images. This results in an increased runtime, but it still discovers only the same semantic crash states as the original prototype using the heuristic.

We additionally analyze how the heuristic reduces the number of in-flight stores considered for crash image generation. In 47 out of 178 applications of the heuristic during all NOVA tests, the recovery code does not read any in-flight stores. We manually verify that these cases occur during journaling in NOVA by checking tracing metadata. In 94 applications of the heuristic, all cache lines with in-flight stores are read. In the remaining 37 heuristic applications, the cross-failure reads make up a strict subset of in-flight stores.

6.3 Performance

Even though performance was not a priority of our prototype, we evaluate its performance to show that the approach is sufficiently fast for testing file systems. We benchmark the Tracer’s performance with the pre-failure command of the “write” test case (see §5.2) on the NOVA evaluation target on an Intel Xeon E5-2620 v4 CPU. We depict the results in Figure 8. Compared to the runtime in raw PANDA (i.e., binary translation without tracing), we observe a slowdown of approximately factor 34. The resulting traces each have

⁵We have only performed a single run for each test case; the generated crash images in each run can slightly vary due to nondeterministic guest execution.

| | $\mu \pm \sigma$ [s] |
|-------------------------------------|---------------------------|
| total elapsed process time | 83.82 ± 0.53 |
| ↳ boot | 1.63 ± 0.03 |
| ↳ Crash Image Generator | 37.87 ± 0.33 |
| ↳ cross-failure tracing (heuristic) | $2.00 \pm 0.28 \times 12$ |
| ↳ Tester | 43.65 ± 0.35 |
| ↳ reset to snapshot & load image | $0.08 \pm 0.01 \times 31$ |
| ↳ run dumper command (PANDA) | $1.04 \pm 0.12 \times 31$ |

Figure 9: Runtimes of the Crash Image Generator & Tester process when processing the trace from Figure 8.

≈ 304438 events and are each ≈ 11.73 MiB in size (in a simple textual format; compressed only ≈ 0.15 MiB).

As the Crash Image Generator and Tester run in the same process in our prototype, we show the execution time of both combined in Figure 9. 12 crash images at fences are used as input for the cross-failure heuristic. The tester processes 31 unique crash images that stem from 77 origins (§3.3) and result in seven unique semantic crash states. We find that the Crash Image Generator and Tester contribute roughly equally to the execution time.

With metadata tracing enabled, the runtime of the Tracer increases significantly to $78.70s \pm 0.75s$, whereas the runtime of the Crash Image Generator and Tester only increases slightly to $84.84s \pm 0.60s$. We argue that performance of metadata tracing mode is not very relevant in practice: Test cases can be tested without metadata tracing, and if a crash consistency bug is uncovered, the affected test cases can be re-run with metadata tracing enabled. Nevertheless, performance can presumably be significantly improved.

In total, all our test cases from Section 5.2 take approximately 24 minutes to execute sequentially on the NOVA evaluation target (without metadata tracing). This includes additional steps such as compressing traces. As test cases can be analyzed in parallel, the whole testing time can be reduced to only a few minutes.

7 Discussion

VINTER fares well at finding new bugs. Its testing pipeline is highly automated and the manual effort required for setup and interpretation of its results is low. In the context of file system testing, the Single Final State property has turned out to be useful, as even if operations are not considered atomic, this property should hold for most file system operations after a call to `sync`. Even in cases where the crash consistency semantics of a file system operation are not clear, VINTER’s representation of semantic crash states makes manual vetting feasible. It has turned out to be useful to test modifying the file system after recovery as part of the state extraction procedure, as some of the bugs only become visible when such an operation fails.

We find that severe crash consistency bugs can be found in NVM file systems by only testing primitive file system operations, with no need for complex interaction between multiple operations. This is contrary to the bugs discovered by CrashMonkey [32], which all appear to involve more complex operation sequences. We see two potential reasons: First, programming for NVM with its byte-level access and persistency semantics is much more complicated than the programming pattern for traditional file systems, where updated sectors are first built in DRAM and then transferred to block storage. Second, the tested file systems are of relatively young age, and are still research prototypes not aimed at production usage (and in case of PMFS, even unmaintained). Testing more complex operation sequences on our evaluation targets might yield even more bugs.

8 Conclusion

Crash consistency is difficult to achieve in non-volatile memory (NVM) software. Existing works on NVM crash consistency testing for kernel software are either inefficient or incomprehensive and not automated, and none consider crash consistency and atomicity among entire operations. This makes existing work unsuitable for comprehensive file system crash consistency testing.

In this work, we have introduced VINTER, a new approach to automatic testing of non-volatile memory software. VINTER consists of an automated testing pipeline that traces executions of full systems that use NVM, simulates crashes, and finally tests the resulting crash images for consistency. We use VINTER to find crash consistency bugs in NVM file systems, including the state-of-the-art file systems NOVA [49] and NOVA-Fortis [50]. Our evaluation uncovers several bugs in all tested file systems, many of them previously unreported. The bugs lead to issues such as data loss, kernel crashes, and unwritable files.

To summarize, our approach is general as it is compatible with different kinds of software including kernel code, easy to apply as it is largely automated and does not need code modifications, and has been shown to find new bugs in existing software.

8.1 Future Work

We lay out possibilities for future work on our subject. We see several areas for improvement:

Support for persistent caches. Some recent processors ensure that all data in the CPU caches is written out to persistent memory in case of a power failure (e.g., eADR [16]). With persistent caches, the programmer no longer needs to use cache flushes to write out data to NVM. This greatly reduces the potential for crash consistency bugs, but does not entirely eliminate them. For example, the NOVA bug we describe in [Section 5.3.2](#)

would still occur on an eADR-enabled system. VINTER could support detecting crash consistency bugs on eADR systems by considering prefixes of all temporal writes instead of arbitrary subsets during crash image generation (§3.3). Choosing subsets of in-flight stores would however still be applicable to non-temporal writes since these are weakly-ordered.

Fault injection. Some NVM software including NOVA-Fortis [50] intends to be resilient against media errors. VINTER could be extended with fault injection to test robustness against corruption.

Heuristics. Bug detection or crash image generation heuristics that observe control or data flow such as those proposed by Fu et al. [11] could be adapted to our approach.

Evaluate NVM operating systems. VINTER could not only be applied to file systems, but also to entire operating systems targeted for NVM, like Bittman et al.'s Twizzler [2]. Twizzler removes the file system from the OS interface, and instead allows applications to directly allocate NVM.

File system test cases. Our file system evaluation could be extended by running automatically generated test cases in a large scale similar to Mohan and Martinez et al.'s CrashMonkey [32].

Traditional file systems. VINTER could also be extended to test traditional block-storage-based file systems without NVM support, bringing features such as automatic atomicity testing over previous work [32]. A generally applicable approach to achieve this would be virtualizing a block storage device and recording a trace of writes as well as flush primitives.

A Artifact Appendix

Abstract

We provide an artifact containing our prototype implementation of VINTER as described in [Section 4](#). The artifact further includes the test cases, configurations, and scripts for reproducing the major parts of our file system analysis (§5) as well as our broader evaluation (§6).

Scope

We aim to achieve two main goals with the artifact. First, it allows reproducing the results of this paper. In particular:

- VINTER can find new bugs in file systems and can help developers with finding the root cause. We provide instructions for reproducing [Figures 4 to 6](#) as well as [Section 5.3](#).
- VINTER can reproduce previously fixed bugs in NOVA. We provide instructions for reproducing [Section 6.1](#).
- VINTER's heuristic is effective at reducing the number of generated crash images without missing semantic states. We provide instructions for reproducing [Section 6.2](#).
- VINTER is sufficiently fast for analyzing file systems. We provide instructions for reproducing [Figures 8 and 9](#).

Second, we provide VINTER for the purpose of analyzing other file systems, in the hope that it will prove useful in developing new NVM file systems.

Contents

Our source code repository (located at `/home/vinter/vinter` in the virtual machine image) contains the following components:

- `README.md` contains general setup information, and `artifact-evaluation/README.md` contains instructions for reproducing the experiments and launching a virtual machine where VINTER is preinstalled.
- `vinter_python/`: The original implementation of VINTER that is used for the analysis in this paper.
 - `pmemtrace.py`: The Tracer component.
 - `trace2img.py`: The Crash Image Generator and Tester components.
 - `trace-and-analyze.sh`: Main script for running the full testing pipeline.
 - `report-results.py`: Script for analyzing output from the testing pipeline.
- `vinter_rust/`: A reimplementaion of VINTER in Rust, with the intention of improved performance and to provide a clean base for future extensions.
 - `vinter_trace/`: The Tracer component.
 - `vinter_trace2img/`: The Crash Image Generator and Tester components. Main entry point for running the full testing pipeline.

- `fs-testing/`: Everything related to the analysis of file systems.
 - `scripts/`: Helper scripts, virtual machine (VM) definitions, and test case definitions.
 - `initramfs/`: BusyBox-based user space of the test VMs.
 - `fs-dump/`: File system state extraction program.
 - `linux/`: Configurations of the Linux kernels we test.
- `panda/`: The underlying full system emulator based on upstream PANDA [9] with patches applied.

Hosting

VINTER's source code is available on GitHub at <https://github.com/KIT-OSGroup/vinter> on the branch `atc22-artifact`, commit `4b7e5651e820ec9ebbe2a7321e28b2748103ab74`.

Additionally, we provide an archive containing a virtual machine image that comes installed with VINTER and all its dependencies at doi:[10.5281/zenodo.6626098](https://doi.org/10.5281/zenodo.6626098). The archive contains instructions for using the virtual machine image.

Abstract

High-performance transaction processing needs to schedule numerous requests from the network. However, such request scheduling comes with costs of complex information gathering and considerable computation. We observe that emerging SmartNICs pose opportunities for transaction scheduling with low overhead. In this paper, we propose AINiCo, which leverages SmartNICs to intelligently schedule incoming transaction requests to CPU cores, minimizing inter-transaction contention with low latency. AINiCo describes the contention according to system states in a way that SmartNICs can efficiently process, and co-designs hardware and software to enable flexible and adaptive scheduling. We implement AINiCo using FPGA-equipped Innova-2 SmartNICs, and our evaluation shows that AINiCo boosts the throughput by $1.30\times \sim 2.68\times$ and reduces the latency by up to 48.8%.

1 Introduction

Transaction processing is a critical building block for many applications such as e-commerce and the stock exchange. Over the last few years, two trends in transaction processing stand out. First, network bandwidth has improved significantly, enabling a surge of transaction requests from the network. Second, modern servers are equipped with numerous CPU cores, providing abundant computing capacity for transaction processing [1–4]. These two trends together pose a crucial problem: *how to schedule each individual transaction request to the most appropriate CPU core?* Using a sophisticated scheduler for transaction processing can mitigate lots of inter-transaction contention (i.e., two transactions concurrently access the same record, and at least one performs a write), reducing transaction aborts/blocking and thus boosting system throughput.

There are two setbacks in realizing efficient transaction scheduling. First, it is hard to gather necessary information

for scheduling in consideration of cost-efficiency. This is because the transaction system is intricate: each request contains a write/read-set with multiple records, and different records have different degrees of hotness [5–7] and affinities. The hotness and affinity are dynamic: for example, in the live selling platform of Kuaishou, product popularity changes over time due to the behavioral uncertainty of users. Second, transaction scheduling incurs considerable computation overhead. For an incoming request, to calculate which CPU core it executes on causes the least contention, the scheduler has to consume computation cycles that are proportional to the number of CPU cores and the request’s write/read-set size.

We observe that exploiting emerging SmartNICs [8, 9] can enable efficient transaction scheduling for two reasons. First, every transaction request/response flows through NICs, so they are the natural place to gather information about scheduling. Second, transaction scheduling requires considerable computation, and SmartNICs are equipped with specialized programmable hardware (e.g., FPGAs), which is adept in fine-grained parallelism. Thus, SmartNICs can serve numerous concurrent scheduling tasks with low latency.

It is non-trivial to design transaction scheduling using SmartNICs. First, we need to describe inter-transaction contention in a hardware-friendly manner so as to squeeze out the parallelism capabilities of the specialized hardware in SmartNICs. Second, it is impossible for SmartNICs to perform all scheduling tasks since CPU-side transaction software owns important information about transaction execution, e.g., the abort rate, which is indispensable for scheduling. Thus, to enable effective transaction scheduling, SmartNICs should cooperate with upper-level transaction software.

We propose AINiCo, a transaction processing system with on-NIC request scheduling. At the core of AINiCo is a SmartNIC-accelerated contention-aware scheduler; it schedules incoming transaction requests to different CPU cores intelligently, minimizing contention between transactions with low latency.

To describe the inter-transaction contention in a hardware-friendly manner, we first classify system runtime states into

*Youyou Lu is the corresponding author (luyouyou@tsinghua.edu.cn).

Figure 1: **The architectures of networked transaction systems (a-d).** (a): A system without scheduling. (b): A system using the static data partitioning method. (c): A system using the batching-based scheduling method. (d): AINiCo.

three types: 1) *request state*, i.e., the set of records accessed by a request and the associated access modes (read and write); 2) *worker state*, i.e., the set of requests being executed by the worker thread on each CPU core; 3) *global state*, i.e., workload characteristics such as hotspots. Then, we encode the above three types of states into compact vectors and translate contention calculation into fast vector computation on SmartNICs. For an incoming request, to calculate its contention against different CPU cores, the scheduler compares the request state and each worker’s worker state, with the global state as the weight. We optimize the calculation process via fine-grained parallelism, ensuring low scheduling latency.

To enable adaptive scheduling for time-varying applications, AINiCo adopts a feedback mechanism from the upper-level transaction software to the SmartNICs. Specifically, software in AINiCo periodically samples the global state as the scheduling guideline and updates the on-NIC scheduler by flexible hardware/software interfaces. In this way, AINiCo can handle dynamic workloads in which hotspots change over time. In addition, via the generalized feedback mechanism, AINiCo can support various concurrency control protocols.

We implement AINiCo with Mellanox InnoVA-2 [8], a SmartNIC equipped with an FPGA. The evaluation shows that AINiCo reduces the abort rate by contention-aware transaction scheduling. AINiCo boosts the throughput by $1.30\times \sim 2.68\times$ than the original system with various concurrency control protocols. In addition, compared with existing static data partitioning methods, AINiCo can handle time-varying and skewed workloads; compared with batching-based scheduling methods, AINiCo schedules requests in real-time and renders latency two orders of magnitude lower.

In summary, we make the following contributions:

- A SmartNIC-enabled contention-aware transaction scheduler that offers low overhead by exploiting the acceleration provided by the FPGA.
- AINiCo, a transaction processing system based on the scheduler, supporting various concurrency control protocols and time-varying workloads.
- An AINiCo prototype on real hardware, exhibiting higher throughput, lower latency, and less abort rate.

2 Background and Motivation

2.1 Contention-aware Scheduling

In an in-memory single-server transaction system, as shown in Figure 1 (a), the NIC receives transaction requests and dispatches them to worker threads. Each transaction request often includes multiple write/read operations to the in-memory records. Worker threads execute transactions using various concurrency control protocols to guarantee transaction isolation. However, concurrent transactions are more likely to be aborted or blocked when there is contention (i.e., two transactions concurrently access the same record, and at least one performs a write). Aborts result in costly retries, and blocking may be cascaded, both of which degrade performance [3]. Therefore, the transaction system needs to minimize contention among concurrent transactions [10–22]. Designing a contention-aware scheduler that schedules conflicting transactions to the same worker threads is meaningful. However, there is an accuracy-overhead trade-off in designing it.

Accuracy-overhead trade-off. A high-accuracy scheduler can assist the majority of requests in selecting an appropriate (i.e., with less contention) worker thread to execute on. To achieve such accuracy, the scheduler incurs much computation overhead. Unlike single-key get/put requests in key-value stores, transaction requests are more sophisticated, containing multiple operations (reads, writes, and range queries) to multiple records. The packet steering method [23, 24] based on RSS [25] or Flow Director [26], which embeds a single key in the packet header as the request dispatching information, is no longer effective for transaction requests. Furthermore, the records have different degrees of hotness (i.e., a small set of records are accessed frequently) and affinities (i.e., two records are often accessed together). The hotness and affinity are also constantly changing. As a result, contention-aware scheduling is time-consuming and induces high overhead for high accuracy.

2.2 Existing Scheduling Methods

We revisit two transaction scheduling methods and show their choices in the accuracy-overhead trade-off.

Static data partitioning method. As shown in Figure 1 (b), recent studies [10–12] maintain a data partition scheme, i.e., a mapping from records to worker threads. Clients know the partition scheme and send transactions directly to worker threads without scheduling. Then, each worker thread executes the transactions that access records in a single partition sequentially. Further, Jepsen et al. [15, 16] use a programmable switch to triage transactions belonging to different data partitions before sending them to the database server.

This method is effective for partitionable workloads where transactions tend to access records in a single partition because it has no scheduling overhead under such workloads. However, this method sacrifices the accuracy for two types of workloads: ❶ workloads that do not have a good partition scheme and ❷ workloads whose record affinities and degrees of hotness are constantly changing. In the first type of workloads, many transactions are cross-partition. These transactions require synchronization between worker threads to access remote partitions. In the second type of workloads, the partition scheme needs to be updated to follow workload changes. Recent studies all use offline computation on workload traces to generate the partition scheme; therefore, this method can not react to the changes in workloads in time and introduces load imbalance when hotspots change.

Batching-based scheduling method. As shown in Figure 1 (c), in this method, worker threads collect a batch of transactions and divide the batch into n groups (n is the worker thread count), intending to minimize contention between groups. After that, each worker thread executes a transaction group with almost no contention. Specifically, recent studies on this method [18–21] use a *graph partition* algorithm that treats transactions as nodes, contention between them as edges, and transaction groups as sub-graphs.

This method is adaptive and can react to changes in workloads. Moreover, it avoids load imbalance by guaranteeing even grouping (i.e., high accuracy). However, it introduces high latency for batching (i.e., high overhead). For example, in a state-of-the-art system, Strife [21], the batch size is 10K, which adds about 5ms latency for requests. This is insufferable for *in-memory* transaction systems [22] which usually have microsecond-level latency.

2.3 Scheduling with SmartNICs

We observe that exploiting emerging SmartNICs (as shown in Figure 1 (d)) is promising to break the accuracy-overhead trade-off due to the following two advantages.

First, every transaction request/response flows through the NIC, so the NIC is the natural place to implement a scheduler, which can route packets to any worker thread and keep track of running/queuing transactions on each worker thread. Then, with this piece of information, NICs have an opportunity to make accurate and adaptive scheduling decisions. Recent studies [23, 27–29] leverage the NIC as a scheduler to dispatch key-value requests, addressing the load imbalance or head-of-

line blocking problems. However, they do not take transaction semantics into consideration.

Second, FPGA-equipped SmartNICs can perform lots of computation to generate accurate scheduling decisions with low latency. FPGA-equipped SmartNICs allow users to customize network processing logic. Also, the FPGA modules can reduce scheduling overhead with hardware acceleration instead of amortizing it by batching transactions. Recent studies [30–36] also show that packet manipulation processes with data/pipeline parallelism (i.e., encryption and serialization) are suitable to be offloaded to the FPGA modules on SmartNICs. Such offloading can accelerate networking and relieve the host-side CPU/memory burdens.

FPGA-equipped SmartNICs can be divided into two categories, on-path and off-path, as shown on the right of Figure 1. They vary in the connection architecture between the FPGA and other NIC components. In an *on-path* SmartNIC, the FPGA is located between network ports and the NIC ASIC. In this type of SmartNICs, the FPGA modules need to process all link-layer network traffic, complicating the FPGA logic. Contrarily, in an *off-path* SmartNIC, the NIC ASIC is the same as that of a standard NIC, and packets are routed to either the host or the FPGA by an on-board PCIe switch. We use an off-path SmartNIC, *Mellanox Innova-2* [8], so that we can focus on the scheduling logic while leaving sophisticated network functions (e.g., reliable delivery and ordering) to the full-fledged NIC ASIC.

Mellanox Innova-2 [8] has a ConnectX-5 NIC ASIC and a Xilinx XCKU15P FPGA. It has two 25Gbps ports and uses PCIe 3.0 $\times 8$ to connect the NIC ASIC, the FPGA, and the CPU. The CPU communicates with the FPGA via MMIO (memory-mapped IO) or the FPGA’s DMA engine. The ConnectX-5 NIC ASIC supports RDMA (remote direct memory access), through which remote clients can read/write the server’s memory while bypassing the server’s CPUs.

Challenges of transaction scheduling with SmartNICs. It is non-trivial to design a transaction scheduler using SmartNICs due to the following challenges: 1) The FPGA is adept in fixed and simple execution flows. We need to describe complicated inter-transaction contention in a hardware-friendly manner to squeeze out the FPGA’s parallelism capabilities. 2) Worker threads have important information about transaction execution, e.g., abort rate, which is indispensable for scheduling. Thus, to enable effective transaction scheduling, worker threads should gather this information as feedback to adjust the scheduler. 3) Transaction systems use various concurrency control protocols and face various workloads; however, the FPGA redesign is costly. It is difficult for an application-specific FPGA-based scheduler to support various transaction systems [37, 38]. To be generalized for all transaction systems, the scheduler design (e.g., request format, scheduling algorithm, and feedback interfaces) should not encode any application-specific characteristics.

Figure 2: A scheduling-enabled RPC with SmartNICs.

3 AINiCo

3.1 Overview

To reduce the inter-transaction contention and break the accuracy-overhead trade-off, we propose AINiCo, a SmartNIC-accelerated contention-aware request scheduler. AINiCo uses hardware acceleration of the FPGA for low overhead and provides generalized software feedback interfaces for high accuracy.

Transaction systems typically provide a *stored procedure* interface, where each type of transaction is compiled into a procedure, and clients issue transactions via remote procedure calls (RPCs). To achieve request scheduling, SmartNICs need to parse the procedure parameters and then detect inter-transaction contention. However, the parameters are application-specific, including keys that the transaction will access, the access modes (read/write), the values that the transaction will write, and so on. The format of the parameters also varies across applications.

Therefore, in order to support diverse applications without encoding application-specific properties, we include a fixed-form header in each request. Clients need to convert the parameters into the fixed-form header. We call this the *request feature vector*. Scheduling also needs the information on running/queuing transactions in worker threads and workload characteristics. AINiCo encodes them in a hardware-friendly manner and leverages the data and pipeline parallelisms of the FPGA to make scheduling decisions (§3.2).

We design a **scheduling-enabled RPC** with SmartNICs as the communication mechanism between clients and the server, allowing the FPGA to receive requests and schedule them. Figure 2 describes its workflow. The server maintains a data buffer on the host memory and a feature vector buffer on the FPGA. To issue a transaction, the client sends the data (1) and the feature vector (2) to their respective buffers via two one-sided RDMA writes posted together. AINiCo’s scheduler (on the FPGA) polls the feature vector buffers to determine the arrival of new requests. The scheduler then selects the most appropriate worker thread based on the request’s feature vector, the runtime states of worker threads, and the workload characteristics. After making the scheduling decision, the

scheduler notifies the selected worker thread via writing its receive completion queue (CQ) (3). The CQ entry includes only the address of request data but not the feature vector. Since RDMA enforces ordered writes, after reading a new CQ entry (4), the worker thread can get the completed data from the RPC data buffers. The worker thread then executes the transaction and replies to the client via a normal RDMA write (5).

To make the scheduler adaptive to workload changes, AINiCo employs a software feedback mechanism (§3.3). It allows the software to use information about transaction execution (e.g., records that cause transactions to be aborted) to guide the scheduler. The feedback interface is generalized for various concurrency control protocols and different workloads. The FPGA fetches the feedback periodically via DMA reads outside the critical path.

3.2 Accelerated Scheduling on The Hardware

To describe the inter-transaction contention and schedule transactions in a hardware-friendly manner, we identify three types of states for scheduling: *request state* (§3.2.1), *worker state* (§3.2.2), and *global state* (§3.2.3). We then encode the states into compact *vectors* and translate the scheduling algorithm into the fast *vector computation*, which is well-suited for the FPGA (§3.2.4).

3.2.1 Request state

AINiCo uses the request state to describe the resources required by a transaction. Clients embed the complex parameters of a transaction request into a request feature vector. Specifically, each feature vector (f_{req}) has L elements¹. We use a mapping function to divide all records into L *groups*. Each element in the vector represents whether the transaction will access the corresponding group of records. The mapping function is the same in all clients. To generate the feature vector, clients enumerate the keys² in the request parameters and set the corresponding elements. Each element can be encoded into either 1-bit or 2-bit element. A 1-bit element describes two access modes: no operation and access (read or write). A 2-bit element describes three access modes: no operation, read, and write, having better expressibility but consuming more space. The scheduler can use the feature vectors of requests to estimate whether contention exists between them. For example, if two requests set the same element in their feature vectors, these two requests might have contention.

The mapping function for generating feature vectors. The mapping function is used to select a group for a given key. Clients use a hash function to calculate a hash value (v) for each key and use $v \% L$ as the group number. Due to hash collisions, clients might map two different keys to the same group.

¹All vectors have a length of L in this paper.

²The primary keys of records.

Figure 3: Mapping collisions of two New-order txns.

To reduce the negative impact of hash collisions, AINiCo imposes two requirements (**R**) on the mapping function. First, transaction systems manage records with different semantics in different tables (e.g., the CUSTOMER table and the ORDER_LINE table in TPC-C) and access records through $\langle table_id, key \rangle$. Therefore, clients should map the keys of different tables into different groups (**R1**). For example, if an application has two tables, the mapping function maps the keys of one table to $\frac{1}{2}$ groups and maps the keys in the other table to the other $\frac{1}{2}$ groups. Second, because different tables can have different sizes (i.e., numbers of records), the number of groups of a table should be proportional to its size (**R2**). We test the CDF of the mapping collisions between New-order transactions in TPC-C, as shown in Figure 3. The mapping function with these two requirements reduces the mapping collisions compared with the simple uniform random hash. Note that when the table count is large, all tables should instead share the feature space since there are not enough elements in the feature vector.

Discussion. There are two corner cases worth discussing when describing the request state.

How to handle data growth. In our current design, the feature vector length L and the key-to-feature mapping function are static at runtime. When the amount of data grows, AINiCo does not need to increase L correspondingly in most cases. This is because the determinant of mapping collisions is the amount of hot data instead of the data in the entire system; only a small amount of data is accessed frequently. However, if changing L or the mapping function is a must (e.g., when the hotspot size changes significantly), AINiCo can reload the on-NIC scheduler with the new configuration (which takes 4.18ms on InnoVA-2 in our evaluation). In that case, clients also need to update the new configuration.

How to describe pre-unknown keys. Clients specify most of the keys of the records that a transaction will access in the request’s parameters. However, some keys are pre-unknown and can only be determined through transaction execution. To describe the required resources for these transactions more accurately, AINiCo employs the following two speculative optimizations. First, for transactions containing range queries, clients randomly generate the keys in the ranges and set the corresponding elements of the request feature vector. Second, for transactions that access records via non-primary keys, the client maintains a secondary-index cache, which maps each non-primary key to a set of primary keys, to determine the records that those transactions will access.

| | no op | read | write | read & write |
|--|-------|------|-------|--------------|
| request feature vector f_{req}^{\rightarrow} | 00 | 10 | 01 | 01 |
| worker feature vector f_w^{\rightarrow} | 00 | 01 | 11 | 11 |

Table 1: Encoding of read and write modes.

3.2.2 Worker state

AINiCo uses the worker state to describe the resources that are being or will be accessed by worker threads. Each worker thread has different running/queuing transactions. Therefore, a state of the i -th worker thread is the union of the feature vectors of its running/queuing transactions. We call it the **worker feature vector** ($f_{w_i}^{\rightarrow}$ for the i -th worker). This vector has the same format as the request feature vector. Further, to allow worker threads to steer requests actively, AINiCo introduces the other worker state, called the **worker steering vector**. Each worker thread maintains a steering vector with 1-bit elements ($s_{w_i}^{\rightarrow}$ for the i -th worker). Worker threads can set their steering vectors via the software feedback interface, which is described in detail in §3.3.2.

How to describe the contention. AINiCo uses the bitwise AND (&) operation to describe the contention between a new request and the running/queuing requests in a worker. When the element in the feature vector is 1-bit, AINiCo encodes request features and worker features in the same way, where 1 represents access (read or write) and 0 represents no operation. The AND operation between request features and worker features estimates all concurrent accesses to the same group. When the element is 2-bit, AINiCo encodes the access modes in request features and worker features in different ways, as shown in Table 1. The result of AND operation between the request features and the worker features describes read/write and write/write accesses to the same group as contention.

How to maintain worker feature vectors. The scheduler maintains a feature vector queue (FVQ) for each worker. The FVQ stores the feature vectors of the worker’s running/queuing requests (f_{req}^{\rightarrow}), in the same order as the requests in the worker’s CQ. The new worker feature vector is recalculated on adding/deleting an f_{req}^{\rightarrow} to/from the worker’s FVQ. Specifically, for each worker, the scheduler keeps two counter vectors. A counter vector counts the number of read requests on different groups, and the other vector counts the write requests. When a request is added/deleted, the scheduler updates the counter vectors and then converts them to the aforementioned worker feature vector with the FPGA’s parallelism.

When a request completes, the scheduler needs to remove its feature vector from the FVQ. One naive method is to let the worker thread notify the scheduler after executing the request. However, it requires an additional MMIO operation, which may slow down the system. AINiCo designs a lazy updating mechanism. Specifically, the scheduler will check the completed requests only when the scheduler pushes a new request to a worker’s CQ. This can be done efficiently through the FPGA’s DMA without invoking the CPU.

| State of | Name | Format | Maintainer |
|----------|----------------------------------|-------------------------------|---------------|
| request | feature: f_{req}^{\rightarrow} | vector: 2-bit \times L | client |
| worker | feature: f_w^{\rightarrow} | vector: 2-bit \times L | scheduler |
| | steering: s_w^{\rightarrow} | vector: 1-bit \times L | |
| global | weight: \vec{W} | vector: 8-bit \times L | worker thread |
| | worker-set table | type \rightarrow worker set | |

Table 2: The states used for making scheduling decisions.

3.2.3 Global state

AlNiCo uses the global state to describe workload characteristics. Real-world applications have skewed access patterns, where some records are accessed frequently (i.e., hotspots). These hot records are the main source of contention. Therefore, in AlNiCo, one of the global states is the **weight vector**. Each element in the vector has 8 bits and is the weight of a group. The element actually represents the total sum hotness of the keys in a group. To make our scheduler adaptive to hotspot changes, the weight vector is dynamically updated by the software, and the feedback interface is detailed in §3.3.1.

The other global state is the **worker-set table**, which stores a set of worker threads for each request type. The scheduler selects a worker only from each request type’s worker set. This is used to avoid the head-of-line blocking for long-running requests, which is described in detail in §3.3.3.

3.2.4 Making scheduling decisions

As summarized in Table 2, states are formatted in vectors with length L, except for the global worker-set table. Therefore, the scheduler can use fast vector computation to make scheduling decisions. For each new request, the scheduler performs the following three steps.

Step#1. The scheduler searches the worker-set table to get the set of workers for this type of transaction.

Step#2. For each worker, the scheduler calculates a **contention rank** ($rank_{w_i}$ for the i-th worker) between the new request and the running/queuing requests in the worker. The contention rank is calculated using the following formula:

$$rank_{w_i} = (\text{sign}(f_{req}^{\rightarrow} \text{ AND } f_{w_i}^{\rightarrow}) \text{ AND } s_{w_i}^{\rightarrow}) \text{ DOT } \vec{W}$$

Here we assume elements in steering vectors ($s_{w_i}^{\rightarrow}$) are 1. When each element in feature vector is 2-bit, AlNiCo needs the **sign** function to transform the result of ($f_{req}^{\rightarrow} \text{ AND } f_{w_i}^{\rightarrow}$) to a vector with 1-bit elements for later calculations. If the input is greater than 0, the result of the **sign** function is 1, otherwise it is 0. This result res_i^{\rightarrow} ³ represents the same groups accessed by the new request (f_{req}^{\rightarrow}) and the i-th worker’s running/queuing requests ($f_{w_i}^{\rightarrow}$). The contention rank of the i-th worker is the weighted sum (\vec{W}) of res_i^{\rightarrow} .

³We denote the results of $\text{sign}(f_{req}^{\rightarrow} \text{ AND } f_{w_i}^{\rightarrow}) \text{ AND } s_{w_i}^{\rightarrow}$ as res_i^{\rightarrow} .

Figure 4: Hardware acceleration for scheduling.

Step#3. The scheduler selects the worker with the *highest* contention rank among n workers⁴ to route the request.

Hardware acceleration. We leverage the FPGA to accelerate the scheduling calculation, including the AND (&) and DOT PRODUCT (·) to compute the contention rank of each worker, and the MAX to select a worker with the highest rank.

(1) We leverage the FPGA data parallelism to calculate all bits simultaneously during the AND operation.

(2) Because each element in res_i^{\rightarrow} is 1-bit, the DOT PRODUCT operation between res_i^{\rightarrow} and \vec{W} is actually a summation operation, which adds a weight value into the sum only if the corresponding bit in res_i^{\rightarrow} is 1. We optimize the summation via a binary tree reduction algorithm. As illustrated in Figure 4, the reduction algorithm executes the + operation in parallel using many computation units. Each unit adds two values in the L inputs, and then the $\frac{1}{2}$ results become new inputs. It repeats this process until there is only one result left. This algorithm only needs to execute $\log_2 L$ times but uses $\frac{1}{2}$ computation units. To save the computation units, we trade memory consumption. Because the weight vector is periodically updated, it is constant for a period. The FPGA stores the results of the DOT PRODUCT between different res_i^{\rightarrow} and the constant \vec{W} in advance. However, res_i^{\rightarrow} has 2^L cases, and it is impractical to store all results. Therefore, we divide res_i^{\rightarrow} into $\frac{1}{8}$ segments. Each segment includes 8 bits and has $2^8 = 256$ results. There are $\frac{1}{8} \times 2^8$ results in total, small enough to be stored in the FPGA’s memory. The FPGA still uses the reduction algorithm to compute the sum of these segments’ results. Storing segment result trades the memory for reducing the number of computation units from $\frac{1}{2}$ to $\frac{1}{16}$.

(3) The MAX operation is to find the highest value among n values. As shown in Figure 4, the FPGA uses the MAX reduction algorithm, which requires only $\log_2 n$ steps.

These hardware optimizations are leveraged to reduce the overhead of making accurate scheduling decisions.

3.3 Adaptive Feedback from The Software

To make the scheduler adaptive to the changes in workload characteristics, AlNiCo allows the software to set the following three states: the weight vector \vec{W} (§3.3.1), the workers’ steering vectors s_w^{\rightarrow} (§3.3.2), and the worker-set table (§3.3.3). AlNiCo provides generalized feedback interfaces to worker threads and uses a lightweight *analyzer thread* to update the

⁴We denote n as the worker count in the following paper.

```

Listing 1: The feedback interfaces and algorithms.

scheduler’s states based on the feedback. Listing 1 shows the feedback interfaces and the algorithms for translating the feedback into the states needed by the scheduler.

3.3.1 Hotness feedback

We define the keys that *cause contention frequently* as the hotspots in the transaction system, instead of the keys that are accessed frequently. The hotspots keep changing over time. AINiCo requires the software to identify the hotspots in real-time and update the weight vector correspondingly.

Hotness feedback interface. We provide a hotness feedback interface as shown in Lines 1-3. Each worker increases the hotness of a key in its exclusive hotness vector (\vec{h}_i) without any coordination with other workers. Different concurrency control protocols invoke the interface in different situations, and we divide them into two cases based on the way they address the contention. First, with OCC and the 2PL that avoids deadlock by wait-free algorithms, transactions might get aborted and re-executed. The worker increases the hotness of the *record that causes the abort*. Second, with the 2PL that holds locks sequentially to avoid deadlock, transactions might be blocked while trying to acquire a lock. Every time a transaction *retries acquiring the lock of a record*, the worker increases the corresponding hotness.

How to update the weight vector. AINiCo employs an epoch-based updating approach. The analyzer thread collects these hotness vectors at the end of each epoch. Further, each worker measures its throughput (tp_i). Then, as shown in Line 13, the analyzer calculates the weighted average (based on tp_i) of workers’ hotness vectors as the global hotness vector (\vec{h}_{all}) and uses it to update the weight vector (Line 15).

When to update the weight vector. AINiCo updates the weight vector only when the real hotspots change. When the system is cold-started (e.g., in epoch 0), requests are randomly scheduled, and therefore \vec{h}_{all} can reflect the real hotspots. However, when the system is stable, due to AINiCo’s effective scheduling mechanism, those hot keys detected right after the cold start no longer cause contention, and their degrees of hotness is low in the new \vec{h}_{all} . In this case, \vec{w} should remain unchanged to keep the scheduler effective.

The software uses throughput decreases or abort rate increases as the signal of the hotspot changes. Line 14 shows how to detect changes in hotspots. In this algorithm, we use the throughput (TP) decreases as the signal. If the throughput decreases significantly, i.e., TP drops by more than a factor of c , AINiCo will store \vec{h}_{all} in a state buffer that can be read by the NIC via DMA.

When the workload is read-intensive, workers increase the hotness every time a record is read. The analyzer simply ignores the workload change signal and always updates the weight vector at the end of epochs. In this way, AINiCo helps worker threads to better leverage cache locality.

3.3.2 Affinity feedback

A contention-aware scheduler not only schedules conflicting transactions to the same workers but also schedules transactions without contention to different workers to make all workers busy. To this end, AINiCo introduces the steering vectors (\vec{s}_w) to guide the scheduler. As shown in the formula in §3.2.4, only if the element in a worker’s steering vector ($s_{w_i}^{\vec{s}}$) is 1, the corresponding element in its feature vector ($f_{w_i}^{\vec{s}}$) is valid. The key idea is to select n (i.e., worker count) **guideline groups** that have the *highest weights* and *do not have affinities with each other*. AINiCo assigns different guideline groups to different workers to achieve the aforementioned goal. Each worker’s steering vector consists of 1-s for its assigned guideline group and all non-guideline groups by default. For other guideline groups, the corresponding element in the steering vector is 0. In this way, the worker will steer transactions accessing its guideline group. Therefore, in a running system, the feature vector of a worker represents the groups that have affinities with the worker’s guideline group.

Affinity feedback interface. To find the n guideline groups, AINiCo needs the affinity characteristics of workloads. We provide the affinity feedback interface (Lines 5-7) that allows users to offer the affinity hint for different workloads.

How to update the steering vectors. As shown in Lines 19-28, the analyzer thread first sorts all groups according to their weights and enumerates them from the group with the highest weight. Then, the analyzer thread checks whether the group has an affinity with the already found guideline groups. If there is no affinity between them, the group will be labeled as a new guideline group.

3.3.3 Reserving workers for long-running transactions

In real-world workloads, some transactions take a long time to finish (e.g., analytical transactions) and block the transactions assigned to the same worker (i.e., head-of-line blocking). For example, a Delivery transaction accesses about 10 times more keys than a New-order transaction. We reserve some workers to handle these long-running transactions, which is similar to the size-aware request scheduling mechanism [39, 40]. We provide an interface to set the worker set for different types of transactions. Our design only sets the worker-set table on the system startup for workloads that have long-running transactions.

4 Implementation

We implement AINiCo on an Innova-2 SmartNIC [8] and use STO [41], a state-of-the-art transaction processing framework, as the backend transaction processing module.

The scheduler on the FPGA. We implement two fundamental drivers for SmartNICs: a PeerDirect driver [42, 43] to build peer-to-peer communication between the NIC ASIC and the FPGA, and a DMA driver [44] to connect the FPGA and the host. Innova-2 holds a Xilinx KU15P FPGA. In our implementation, the feature vector length L is 512, and we encode read/write modes to the same bit to save feature space. The clock frequency is 250MHz. With these configurations, AINiCo consumes 54 cycles for each request to make the scheduling decision. AINiCo updates global states every 1024 requests (every 22ms) in the background, consuming 1184 cycles. Therefore, we set the epoch size for gathering the feedback in software to 20ms. The implementation consumes 159K (30.48%) LUTs, 157K (15.10%) FFs, and 678.5 (68.95%) BRAMs. We evaluate the computation cycles and resource usage with different feature vector lengths in §5.6.

The transaction processing module on the host. We choose STO as our backend transaction processing module because it implements various CC protocols in the same framework and is high-performance. To use STO, we locate the contention handling function in the framework and then add feedback interface codes to these functions. The parameters of this feedback interface are the records that triggered the contention handling function. On the client side, we do not modify the original request format of the stored procedure, and we only add the field for the feature vector in the request header. We use the following four concurrency control (CC) protocols in the STO framework:

- OCC: it is based on Silo [45], which avoids allocating global timestamps to improve multi-core scalability.
- TicToc [46]: it is an OCC variant that assigns commit timestamps dynamically according to read/write set.
- MVCC: it is based on Cicada [47], which optimizes the management of the timestamps and multi-version values.
- 2PL [48, 49]: it uses NO_WAIT to avoid deadlock; when a transaction fails to acquire a lock, it immediately aborts.

All four concurrency control protocols run at the serializable isolation level. The table indexes use Masstree [50], which supports range queries.

5 Evaluation

We evaluate AINiCo under various workloads and seek to answer the following five questions:

1. How does AINiCo perform compared with existing transaction scheduling methods (§5.2)?
2. How does AINiCo react to dynamic workloads (§5.3)?
3. Why are SmartNICs necessary for the contention-aware request scheduling (§5.4)?
4. How compatible is AINiCo with various concurrency control protocols (§5.5)?
5. What are the overhead and the limitation incurred by the on-NIC scheduler in AINiCo (§5.6)?

5.1 Experimental Setup

Experimental environment. We run all experiments on three machines, one as the server and two as clients.

Hardware settings. Each machine is equipped with two 12-core Xeon E5-2650 v4 2.20GHz CPU sockets, PCIe 3.0 interfaces, and memory of 128GB. The database server is equipped with a dual-port 25Gbps Innova-2 SmartNIC. Each client is equipped with one 100Gbps Mellanox ConnectX-5 NIC. They are connected by a 100Gbps Mellanox switch.

Software settings. Each client thread issues up to 4 transaction requests simultaneously (i.e., the queue depth is 4). We adjust the number of clients and the number of asynchronous requests per client to change the test pressure. The server uses 20 cores for worker threads, 2 cores for long-running transactions in TPC-C workloads, and one core for the analyzer thread and performance measurement. For a fair comparison, the competitors use the RDMA-based RPC with optimizations from previous RDMA systems [51–58], and only use the normal ASIC part of the Innova-2 NIC. We evaluate the performance of this RPC against our scheduling-enable RPC in §5.6.

Workloads. We use the following benchmarks:

TPC-C [6] simulates the activity of a wholesale supplier with five types of transactions. We use the full-mix TPC-C. AINiCo reserves two cores for the long-running delivery transactions. **YCSB-T** is a transactional extension of YCSB, which is a popular KV store benchmark [59]. It has 20 tables as many as the worker threads, and the key space is 100M. Each record contains an 8-byte key and a 384-byte value [39, 60]. Each transaction accesses 16 records in a single table, and the keys are generated according to the Zipf distribution ($\theta=0.99$). **YCSB-HOT** is a dynamic workload based on YCSB-T. Different from YCSB-T, it has 100 tables, and 20 tables are hot at one time. The hot tables are changed every two seconds to

Figure 5: **Throughput.** The wh in TPC-C is the number of warehouses, (a): the low-contention workload, (b): the skewed workload under Zipf $\theta=0.99$, (c): the high-contention workload. The w in YCSB is the percentage of write operations.

simulate the changes in time-varying applications. Keys are generated according to the Zipf distribution ($\theta=1.2$).

Competitors. We compare AINiCo with five systems: a baseline system without scheduling, two systems using existing scheduling methods, and two CPU-based versions of AINiCo. NetSTO is a baseline system in which clients randomly select a worker to send transaction requests without scheduling. StaticPart is a system using the static data partitioning method. For TPC-C workloads, StaticPart partitions data based on the warehouse ID [12]. For YCSB-T and YCSB-HOT workloads, StaticPart partitions data based on the ID of tables. Strife [21] is a system using the batching-based method. The batch size is 10K, and the batch waiting time is 5ms, the same configuration as in Strife’s paper. To support batching, the queue depth in clients is 1K.

AINiCo-CPU-2 is a CPU-based version of AINiCo, which reserves two dedicated threads to execute the scheduling logic. Each scheduler thread connects to half of the clients and communicates with the workers through separated message queues. The worker/global states are shared by the scheduler threads and updated with atomic operations.

AINiCo-CPU-N is the other CPU-based version of AINiCo. It co-locates the worker logic and scheduler logic in each thread, where they multiplex the CPU resource. All threads share the worker/global states. The client connections are evenly distributed among threads. Each thread can make scheduling decisions and delegate requests to others as a scheduler.

5.2 Overall Performance

We first evaluate the peak throughput of NetSTO, StaticPart, Strife, and AINiCo with various workloads in Figure 5. Then we evaluate the latency of different types of transactions under TPC-C by varying request pressure in Figure 6.

Throughput under TPC-C. We evaluate TPC-C under different levels of contention by varying the number of warehouses. We set the warehouse count to 20 and 2 to simulate low-contention and high-contention scenarios. We also introduce a skewed TPC-C, which has 20 warehouses. In this skewed TPC-C, clients select the warehouse according to the Zipf distribution with $\theta = 0.99$. In StaticPart, when the warehouse count is equal to the worker count (20), each worker manages an exclusive warehouse, and when the warehouse

count is 2, every 10 workers manage a warehouse. For a fair comparison, StaticPart, Strife, and AINiCo all reserve 2 worker threads for long-running transactions. Figure 5 (a)-(c) show the throughput of TPC-C under these configurations, and we have the following two observations.

First, in the low-contention workloads (Figure 5 (a)), StaticPart has the highest throughput, outperforming NetSTO, Strife, and AINiCo by 1.30 \times , 1.11 \times , and 1.06 \times , respectively. This is because only 10% of the transactions are cross-warehouse transactions, and the warehouse count is the same as the worker count, which is a good case for the static data partitioning method. The transaction grouping algorithm in Strife and the feedback mechanism in AINiCo cost the CPU resources that are originally used for transaction execution. In the skewed workloads (Figure 5 (b)), the throughput of StaticPart is only 47% of NetSTO. This is because clients access hot warehouses while the data partition in StaticPart is static, which results in load imbalance.

Second, in the high-contention workloads (Figure 5 (c)), 1) AINiCo improves throughput by 2.46 \times compared with NetSTO. This is because the contention-aware scheduling reduces the contention between the running transactions and saves the CPU resources to execute more transactions. 2) The throughput of AINiCo is 2.41 \times higher than StaticPart. This is because the workload is not partitionable and there is still a lot of contention between concurrent transactions.

Throughput under YCSB-T. Figure 5 (d)-(f) show the throughput under YCSB-T with different read/write ratios. We have the following two new observations.

First, all scheduling methods do not have benefits under the read-intensive workload (Figure 5 (d)). This is because 1) there is less contention for read-intensive transactions; 2) the throughput of this workload is bound by the bandwidth of the NIC (i.e., 50Gbps); 1Mops/s throughput in this workload requires about 45.6Gbps outbound bandwidth to transmit data.

Second, the highest throughput of write-intensive workloads (Figure 5 (f)) is bound by the NIC in AINiCo. However, NetSTO can not use the full bandwidth because this workload causes more contention (especially the write-write contention) than the read-intensive one.

Latency under TPC-C. We evaluate the latency distribution for New-order transactions and Delivery transactions (long-running) with varying throughput. Figure 6 shows the median

Figure 6: Latency of New-order and Delivery transactions under TPC-C (2 warehouses).

(P50) and 99th percentile (P99) latency, and we have the following two observations.

First, as shown in Figure 6, when the throughput is low, the median latency of New-order in AINiCo ($24.1\mu s$) is higher than that in NetSTO ($23.6\mu s$). This is because the requests in AINiCo have extra latency for scheduling logic and two extra PCIe communication latency for the off-path SmartNICs. As the throughput increases, the New-order median latency in AINiCo is lower than NetSTO because the reserving worker threads for long-running transactions prevent them from blocking other normal transactions.

Second, in NetSTO, before the throughput reaches the peak, the latency increases faster than in AINiCo. This is because the contention blocks transactions or causes them to retry, increasing the latency of the running transactions and blocking subsequent requests. Under a similar throughput of AINiCo (0.78Mops/s) and NetSTO (0.71Mops/s), AINiCo reduces the median latency of New-order from $51.8\mu s$ to $26.5\mu s$.

In addition, median and P99 latency in Strife exceed $7ms$, larger than the batch waiting time ($5ms$). In Strife, the median latency of New-order is between $7.00ms$ and $19.92ms$, and the P99 latency is between $12.54ms$ and $25.18ms$, which are not plotted in the figure to avoid obscuring other results. This is because the end-to-end latency includes the network stack latency, the batch time, the transaction grouping time, and the transaction execution time. AINiCo does not sacrifice the request latency: at the peak throughput, the P99 tail latency of the New-order transaction is no more than $1.17ms$, and the median latency is only $72.7\mu s$.

5.3 Dynamic Workloads

We evaluate AINiCo’s ability to adapt to dynamic workloads by changing the hot tables in YCSB-HOT. We run YCSB-HOT with a 50/50 read/write ratio.

Figure 7 shows the throughput over time, from which we have the following three observations.

Figure 7: YCSB-HOT throughput over time. Hot tables change every 2s; measuring the throughput every 10ms.

First, AINiCo takes about $150ms$ to adapt to the changes of hot tables. At the beginning of changes, the throughput drops to the lowest point, even worse than NetSTO. This is because the weight vector fails to reflect the conflicting hotspots in the new hot tables. The steering vectors based on the historical hotspots can not guide the scheduling. Before adjusting the scheduler to fit the new workloads, AINiCo suffers performance jitters. This is because the feedback in AINiCo reflects the workload characteristics over time, and it takes a while to make the characteristics of old hot tables fade away. Second, Strife reacts more quickly to dynamic workloads without experiencing throughput degradation. This is because the results of transaction grouping in Strife are based on the information in a batch and do not rely on the historical information of the workloads. However, the median/P99 latency (at the peak throughput) of AINiCo and Strife are $72.6\mu s/1.66ms$ and $12.21ms/15.23ms$, respectively. This is because Strife introduces extra latency due to batching. Third, StaticPart performs worse than NetSTO and varies with the workload changes. This is because the hot tables cause the load imbalance problem in this static data partition method.

In summary, according to §5.2 and §5.3, the static data partition methods are the best for the partitionable workloads, but they can not handle skewed or dynamic workloads. The batching-based scheduling methods can handle various workloads, but they introduce orders of magnitude higher latency for requests. Thanks to SmartNICs, AINiCo can handle skewed or dynamic workloads with low latency.

5.4 Comparison with CPU-based AINiCo

We demonstrate the necessity of SmartNIC-accelerated design for contention-aware scheduling by comparing it with two versions of CPU-based AINiCo.

Figure 8 shows the throughput of CPU-based AINiCo with varying worker thread count. The workload is TPC-C with 2 warehouses. We have the following three observations.

First, AINiCo-CPU-2 brings an improvement in throughput when the worker thread count is small. However, with more worker threads, the performance decreases. This is because two scheduler threads have limited computing resources, and the scheduling complexity increases linearly with the number of worker threads. As a result, the CPU can not accelerate the scheduling computation.

Figure 8: TPC-C (2 warehouses) throughput with four different concurrency control protocols.

Second, AINiCo-CPU-N is not as good as AINiCo-CPU-2 when the worker thread count is small because the scheduling consumes the workers’ resources. It improves the throughput compared with NetSTO because its scheduling overhead is less than the overhead for transaction aborts/blocking. Moreover, its throughput is scalable with the thread count because the resources for the scheduler increase linearly with the thread count.

Third, the improvement of the AINiCo-CPU-N version is small. The throughput of the scheduler itself is not the bottleneck in AINiCo-CPU-N, but it can not enjoy the acceleration of the FPGA. The scheduling logic costs lots of CPU resources. AINiCo speeds up individual request scheduling by fine-grained parallel computation, and the computation of multiple requests is pipelined. These provide higher performance with less CPU resource cost.

5.5 Generality of AINiCo

We demonstrate the generality of AINiCo by changing the concurrency control protocols in STO. Figure 8 shows the throughput with varying worker thread count and the four CC protocols described in §4. The workload is TPC-C with 2 warehouses. Note that, since the 2PL implementation in STO has performance abnormalities under full-mix TPC-C, we only evaluate the New-order transactions for 2PL (Figure 8 (d)). Comparing AINiCo with NetSTO, we have two observations:

First, AINiCo brings performance improvement for these 4 CC protocols. With 20 workers, AINiCo improves the throughput by 2.45× (OCC), 1.77× (TicToc), 2.45× (MVCC), and 2.28× (2PL), respectively. This is because AINiCo provides a generalized hotness feedback interface and affinity feedback interface to generate the worker states and global states. The feedback mechanism in AINiCo is generalized for various concurrency control protocols.

Figure 9: RPC throughput (a) and median latency (b) with varying request sizes.

| | | L=128 | L=256 | L=512 | L=1K | L=4K |
|--------------------|----------|-------|---------|---------|----------|-------|
| Accuracy rate | TPC-C | 22.7% | 36.7% | 59.8% | 85.5% | 99.9% |
| | YCSB-T | 5.2% | 6.5% | 9.9% | 28.4% | 84.4% |
| | YCSB-HOT | 17.6% | 20.7% | 29.4% | 42.7% | 79.8% |
| Computation cycles | | 37 | 37 | 54 | 101 | N/A |
| BRAM/LUT/FF(%) | | 6/2/9 | 10/3/11 | 16/5/16 | 30/10/26 | N/A |

Table 3: The trade-off of feature vector length L.

Second, 2PL performance is worse than other protocols. This is because 2PL needs to write shared memory to acquire the read lock, while the weakness of OCC’s high rollback overhead is negligible in the in-memory system. MVCC has the extra overhead of maintaining version information, so it has lower overall throughput than OCC and TicToc.

5.6 Overhead and Limitation

We evaluate the overhead of AINiCo and discuss its limitation.

Overhead of clients. The client specifies the request feature vector when serializing a transaction into a network message. It takes about 23ns for each key in the transaction parameters.

Overhead of SmartNICs. Figure 9 shows the performance of RDMA-RPC and AINiCo under a micro-benchmark, where the server sends an 8-byte reply to clients immediately as soon as receiving a request. When the request is less than 2KB, the IOPS and latency are limited by the on-NIC scheduler. This is because AINiCo needs extra bandwidth to send the feature vector, and the off-path SmartNIC introduces additional latency.

Overhead of server feedback. The evaluation shows that AINiCo uses only 1.2% of the CPU resources for the software feedback since the FPGA completes most computations for scheduling. However, the CPU-based AINiCo (AINiCo-CPU-N version) takes 27.7% of the CPU resources (i.e., scheduling overhead) to make scheduling decisions, which overshadows the scheduling benefits. This illustrates the need for using SmartNICs to reduce scheduling overhead.

The trade-off of feature vector length L. Table 3 shows the trade-off for choosing the feature vector length L, where the accuracy rate means the proportion of keys detected as the contention that are truly contention. We have two observations. First, a larger feature vector length L improves the accuracy rate because it reduces mapping collisions in features. Second, the scheduler IP core in AINiCo requires more computation cycles and FPGA resources, and they increase linearly with

Figure 10: YCSB-T (W:50) throughput (a) and contention detection accuracy rate (b) with varying θ .

the feature vector length L . The theoretical maximum of L is limited by BRAM resources that are used to receive request feature vectors and store scheduler runtime states. We can sacrifice computation optimization or use on-NIC DDR4 (8GB in Innova-2) as storage resources to support a larger L .

Limitation. Based on all experiments in this section, we discuss the following two limitations. 1) AINiCo can not improve the performance of uniform workloads. Figure 10 shows the throughput and the accuracy rate of contention detection with different θ under YCSB-T(W:50%). We observe that only when θ is higher than 0.8, the feature vectors can reflect the contention between requests. This is because, with the more skewed access pattern, the mapping collisions are fewer, and the weights of groups are more distinguishing. 2) AINiCo can not improve the performance of the workloads whose throughput is limited by the NIC bandwidth. We focus on workloads whose throughput is limited by contention because AINiCo consumes additional bandwidth for feature vectors.

6 Related Work

In-network scheduling. There have been intensive evolution efforts in application layer network scheduling, focusing on core affinity, load balance, head-of-line blocking, and in-network transaction coordination.

Core affinity. RSS [25] and FlowDirector [26] dispatch packets based on hashing header fields. MICA [23] uses RSS to assign single-key KV requests to cores based on the key hash partitioning for object-level core affinity. RSS++ [61] achieves dynamic load balance by RSS indirection and supports stateful flow migration by optimizing state transfers among cores. Different from them, AINiCo focuses on contention-aware scheduling for transaction requests.

Load balance. Recent studies [62–64] achieve μ s-scale SLOs through dynamic core scheduling or request scheduling. Humphries et al. [27] offload Shinjuku [64] to SmartNICs. RPCValet [28] and R2P2 [65] dispatch stateless RPC by emulating the theoretically optimal single-queue scheduling policy on NICs and programmable switches, respectively. RackSched [66] is a rack-level service scheduler with two-layer (i.e., inter/intra-server) scheduling.

Head-of-line blocking. In Minos [39] and DARC [40], KV requests for records of different sizes go to different cores to avoid blocking small requests by long-running requests.

In-network transaction coordination. Recent work offloads the transaction coordination to programmable switches [67–69] and client-side SmartNICs [70] to reduce the network overhead of distributed transactions. AINiCo focuses on scheduling single-machine transactions to different CPU cores.

Transaction scheduling. Recent work for transaction processing can be categorized into inter-transaction scheduling and intra-transaction scheduling. AINiCo focuses on inter-transaction scheduling, which schedules each entire transaction to the most appropriate CPU core.

Inter-transaction scheduling. The common principle of batching-based scheduling methods is to make each group almost conflict-free, and they differ in the approaches to residual conflicts. Calvin [71], LADS [19], and QueCC [18] keep track of the dependencies between transaction groups and wait for the completion of dependent transactions. Ding et al. [20] present a method that retries conflicting transactions at a higher priority in the next batch. Further, Jepsen et al. [15, 16] use a programmable switch to triage transactions belonging to different static data partitions before sending them to the database server.

Intra-transaction scheduling. A series of studies use strategies including tracking transaction dependencies [72], exploring the operation commutability [73], reading values from the write buffer [20], and releasing the lock in advance [74] to schedule each read/write operation. Polyjuice [75] uses machine learning models to specify different execution policies for each operation. Moreover, some studies focus on the order of locks; QURO [76] allows transactions that are more likely to block the system to hold locks, while Chiller [77] changes the lock order to reduce the locking time of hot records. Their intra-transaction scheduling is complementary to AINiCo.

7 Conclusion

This paper presents AINiCo, a transaction system that leverages SmartNICs to intelligently schedule incoming transaction requests to CPU cores, minimizing contention with low latency. AINiCo describes the contention in a hardware-friendly manner so that specialized hardware can efficiently make scheduling decisions, and co-designs hardware and software to enable flexible and adaptive scheduling. Evaluation with real hardware (Innova-2) shows that AINiCo reduces the contention between the running transactions and significantly improves performance.

Abstract

Network bandwidth is improving faster than the compute capacity of the host CPU, turning the CPU into a bottleneck. As a result, SmartNICs are often used to offload packet processing, even application logic, away from the CPU. However, today many applications such as Artificial Intelligence (AI) and High Performance Computing (HPC) rely on clusters of GPUs for computation. In such clusters, the majority of the network traffic is created by the GPUs. Unfortunately, commercially available multi-core SmartNICs, such as BlueField-2, fail to process 100Gb network traffic at line-rate with its embedded CPU, which is capable of doing control-plane management only. Commercially available FPGA-based SmartNICs are mainly optimized for network applications running on the host CPU. To address such scenarios, in this paper we present FpgaNIC, a GPU-oriented SmartNIC to accelerate applications running on distributed GPUs. FpgaNIC is an FPGA-based, GPU-centric, versatile SmartNIC that enables direct PCIe P2P communication with local GPUs using GPU virtual address, and that provides reliable 100Gb network access to remote GPUs. FpgaNIC allows to offload various complex compute tasks to a customized *data-path accelerator* for line-rate in-network computing on the FPGA, thereby complementing the processing at the GPU. The data-path accelerator can be programmed using C++-based HLS (High Level Synthesis), so as to make it easier to use for software programmers. FpgaNIC has been designed to explore the design space of SmartNICs, e.g., direct, on-path, and off-path models, benefiting different type of application. It opens up a wealth of research opportunities, e.g., accelerating a broad range of distributed applications by combining GPUs and FPGAs and exploring a larger design space of SmartNICs by making them easily accessible from local GPUs.

1 Introduction

While the computing capacity of CPUs is growing slowly and mostly either through parallelism (SIMD, multi-core) or specialization (GPGPU, security or virtualization support), network bandwidth is growing obviously faster. 100Gbps

NICs are common and soon 400Gbps will be available [46]. This growing gap between network bandwidth and compute capability is being addressed through offloading of network functions to the Network Interface Card (NIC), so called SmartNIC [13, 14, 19, 36, 45], which frees up significant CPU cycles and provides better hardware to keep up with the growing network traffic and its often strict requirements in terms of bandwidth and latency.

Modern GPUs provide an order of magnitude higher memory bandwidth and higher compute capacity than modern CPUs. As a result, GPUs have become a key element in, e.g., Artificial Intelligence (AI) and High Performance Computing (HPC) applications that are both compute- and memory-bound [4]. Since a multi-GPU server is often not enough to cover the computing power needed in many AI, graph, and HPC applications, current solutions are typically based on a cluster of GPUs (e.g., [27, 58, 78]), with the GPUS generating the majority of the network traffic in such systems.

In this paper, we present the design of a 100Gb GPU-centric SmartNIC to serve distributed applications running on GPUs. From a GPU's perspective, such a SmartNIC should 1) enable the GPU directly triggering doorbell registers and polling on status registers on the SmartNIC without CPU intervention (**G1**); 2) use the GPU virtual address space to directly access GPU memory via Peer-to-Peer (P2P) communication without CPU intervention (**G2**); 3) implement in hardware the full network stack to ensure low latency and high throughput (**G3**); 4) support application logic offloading to a software-defined and hardware-accelerated data-path accelerator, i.e., *on-NIC* computing processing 100Gb network traffic at line-rate (**G4**)¹; and 5) The data-path accelerator should be easily programmed by system programmers (**G5**). Commercially available SmartNICs are not able to satisfy all these goals as they are not optimized for GPUs. In the following, we analyze existing multicore and FPGA-augmented SmartNICs that motivate FpgaNIC.

Multicore SmartNIC. A multicore SmartNIC, such as

¹In the paper, we use on-NIC computing module and data-path accelerator interchangeably.

Table 1: Comparison of FpgaNIC with existing SmartNIC types for GPUs. ✓ indicates full support, ✗ indicates no support, and ✓ indicates partial support.

| | Multicore SmartNIC [44] | FPGA-aug. SmartNIC [45] | Ours |
|--------------------------------------|-------------------------|-------------------------|------|
| Control plane offload (G1) | ✗ | ✗ | ✓ |
| Access GPU with virtual address (G2) | ✓ | ✗ | ✓ |
| 100Gb transport offload (G3) | ✓ | ✓ | ✓ |
| 100Gb data-path accelerator (G4) | ✗ | ✓ | ✓ |
| High programmability (G5) | ✓ | ✗ | ✓ |

BlueField-2 [44], combines a multicore CPU, e.g., ARM, with an ASIC network controller. It introduces an additional hop to implement the smart function using a multicore CPU, which features two DDR4 channels for staging. This allows to map a broad range of applications on multicore SmartNICs. Therefore, its high programmability **G5** is fully supported. However, it increases processing latency and multicore CPU’s memory bandwidth can easily become a performance bottleneck. BlueField-2 has 27.3GB/s achievable memory bandwidth under a benchmarking tool sysbench [1], indicating that directly staging 100Gbps data stream at the NIC CPU already overwhelms BlueField-2, matching the findings in [40]. Therefore, it cannot act as a 100Gb data-path accelerator **G4**. To our knowledge, the multicore SmartNIC is controlled from the host CPU, so **G1** is not yet supported. The network transport is implemented with the packet processing engine with necessary control on the host (or ARM) CPU, so **G3** is partially supported. Finally, the ASIC network chip of multicore SmartNIC supports NVIDIA GPUDirect [52], which enables direct PCIe P2P data communication to a GPU, so **G2** is fully supported.

FPGA-augmented SmartNIC. An FPGA-augmented SmartNIC combines a hardware-programmable FPGA with an ASIC network controller. For example, Mellanox Innova-2 [45] is an FPGA-augmented SmartNIC featuring a network adapter ConnectX-5 and an Xilinx FPGA. ConnectX-5 consists of a 100Gbps InfiniBand/Ethernet interface for networking and a PCIe Gen4x8 interface for communicating with the host CPU. The FPGA communicates with ConnectX-5 via a PCIe x8 Gen4 link, so processing packets on the FPGA adds considerable latency to the packets and processing cannot happen at line rate because Innova-2 has limited PCIe link bandwidth between the FPGA and ConnectX-5. Therefore, Innova-2 can only acts as a partial 100Gb data-path accelerator **G4**. **G1** is not yet supported, **G2** is not supported, **G3** is partially supported, and the high programmability **G5** is not supported.

Given the limitations of existing NICs, in this paper we present FpgaNIC, a full-stack FPGA-based GPU-centric versatile SmartNIC that opens up the opportunity to explore a *large design space around SmartNICs* due to the FPGA’s reconfigurable nature and efficient *FPGA-GPU co-processing* while achieving all the five goals mentioned above in a single

system. We have implemented FpgaNIC as a composable architecture that consists of a *GPU communication stack*, a *100Gb hardware network transport*, and an *On-NIC computing (ONC)*, i.e., data-path accelerator.² The GPU communication stack enables offloading of control plane onto GPUs (**G1**) and thus *for the first time* enables local GPUs directly to manipulate SmartNIC without CPU intervention, and enabling the FPGA-based SmartNIC *for the first time* to use GPU virtual address to directly access GPU memory via PCIe P2P communication (**G2**). The 100Gb hardware network transport enables efficient and reliable 100Gb network communication with remote GPUs (**G3**). Moreover, FpgaNIC adopts a layered design to allow developers to easily explore the design space of SmartNIC models (i.e., direct, off-path, and on-path) to benefit their application, where different applications favor a different SmartNIC model. FpgaNIC allows to prototype applications that can eventually be migrated to hardened SmartNICs. Implementing a data-path accelerator on an FPGA can easily satisfy line-rate processing requirement (**G4**) due to its hardware implementation, while FpgaNIC allows to use C++-based High Level Synthesis (HLS) so as to provide high programmability (**G5**). As such, in the context of FPGA-GPU co-processing, the GPU provides to applications expressiveness and computing flexibility, while the FPGA provides a flexible network infrastructure and the necessary ONC. FpgaNIC results in significant end-to-end performance improvements as data can be processed as it flows from/to the GPU in a streaming manner and without involving the CPU.

We have prototyped FpgaNIC on a PCIe-based Xilinx FPGA board Alveo U50 [74], whose UltraScale+ FPGA features a 100Gbps networking port, a X16 PCIe Gen3, and 8GB HBM. Its form factor is half-length, half-height and its Maximum Total Power (MTP) is 75W, allowing it to be easily deployed in any CPU server.³ In addition to comprehensive benchmarking, we validate the **versatility** and **potential** of FpgaNIC by implementing use cases for all three models: GPU-centric networking (in a direct model), a collective primitive AllReduce (in an off-path model), and cardinality estimation on incoming streaming data (in an on-path model). The experimental results show that FpgaNIC is able to efficiently support all three SmartNIC models at the full line rate of 100 Gbps Ethernet. Particularly, FpgaNIC-enhanced AllReduce almost reaches the maximum theoretical throughput when performing on a distributed pool of eight RTX 8000 GPUs, while requiring fewer than 20% of the FPGA resources on the U50 board. It indicates that, even when considering the full network stack offloading, it has sufficient FPGA resources to allow more aggressive offloading, e.g., the Adam

²In the paper, we use on-NIC computing module and data-path accelerator interchangeably.

³We have also migrated FpgaNIC onto the Alveo U280 FPGA board [73] with minor modifications affecting the FPGA pin mapping. Though we have not ported FpgaNIC to Intel FPGA boards yet, we believe that it requires only a small amount of effort to do so. We leave the porting to future work.

optimizer [31].⁴ As such, FpgaNIC enables efficient FPGA-GPU co-training on Deep Learning models. We leave this exploration to future work.

2 Design and Implementation of FpgaNIC

2.1 Design Challenges

We highlight four concrete research challenges we faced in designing FpgaNIC.

C1: How to Enable the FPGA to Access the GPU Virtual Address? Enabled by NVIDIA GPUDirect [52], the DMA engine in the PCIe IP core allows the FPGA to efficiently transfer data from and to GPU memory via issuing a DMA read/write command that consists of a starting physical address and length (no larger than a GPU page size). However, doing so in the context of SmartNIC raises two challenges. First, a GPU program manipulates GPU virtual address rather than physical address, so the FPGA should work on GPU virtual address to be consistent with the view of GPUs. Second, a single contiguous virtual address space needs not to be physically contiguous on GPU memory, and the typical memory page size is 64KB on modern GPUs as they do not yet support huge pages, making TLB management really challenging, especially when the required number of TLB entries is large.

C2: How to Enable Efficient Reliable Network Transport between Distributed GPUs? Modern GPUs have become a key compute engine to power AI and HPC applications due to its massive parallel compute capacity and huge memory bandwidth. AI and HPC applications typically need reliable network communication between distributed GPUs to realize GPU-accelerated cluster computing. However, GPUs are not originally designed for reliable network transport [28, 43] since reliable networking reduces the degree of parallelism and requires a complex flow control, e.g., retransmission.

The straightforward approach to realize network transport is to implement it on the CPU. Such a CPU-based approach consumes several CPU cores to implement a 100Gbps network transport layer. Furthermore, the network operations are initiated from the GPU, incurring longer network latencies. Instead, we offload the implementation of the reliable network transport to the FPGA to make the data plane fully bypass the host CPU. Fortunately, there is a growing amount of open-source FPGA-based 100Gb network transports [3] such as the TCP/IP stack of [57, 60] and the RoCEv2 stack used in [62]. However, how to enable the GPU to efficiently manipulate the reliable hardware transport on the FPGA becomes a new challenge.

C3: How to Enable High-level Programming Interface for FpgaNIC? The traditional programming interface on FPGAs use tedious, low-level, cycle-sensitive hardware de-

⁴The total offloading tasks (communicator and optimizer) in FpgaNIC do not need any GPU computing cycles that can be used for compute-intensive and memory-intensive forward and backward propagation.

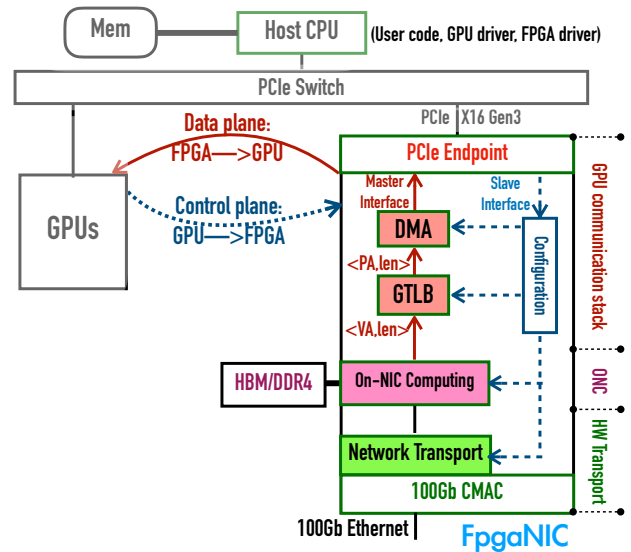

Figure 1: System architecture of FpgaNIC, which enables control/data plane offloading and reliable network transport offloading, and enables on-NIC computing module to process data from network at line rate. Moreover, FpgaNIC enables a large SmartNIC design space exploration.

scription language (HDL), which hinders FPGAs from wide adoption by software programmers. Therefore, the programming interface of FpgaNIC cannot be HDL so as to attract more system programmers.

C4: How to Enable Various SmartNIC Models? Based on the location of the smart function, SmartNICs can be categorized into three models: direct, on-path and off-path. A direct SmartNIC allows local GPUs to directly manipulate the network transport to realize, e.g., GPU-centric networking.

An on-path SmartNIC directly works on each network packet according to the corresponding smart function so that packets do not need to be staged, avoiding unnecessary additional latency in calling the smart function. However, its application scope is limited since it cannot handle complex functions as they are directly on the critical path of the network packets.

An off-path SmartNIC introduces an additional hop to implement the smart function using, e.g., a multicore CPU, which features two DDR4 channels for staging. This allows to map a broad range of applications on off-path SmartNICs. However, multicore CPU’s memory bandwidth can easily become a performance bottleneck when processing 100Gb network traffic using the multicore CPU [40].

Different smart functions favor different SmartNIC models. For example, an on-path approach is preferred when offloading database’s filter operator [61] while AllReduce [4] is better mapped to off-path SmartNICs. Instead of using specialized SmartNICs, we argue for a flexible architecture that enables all this models.

2.2 Main Architecture of FpgaNIC

To address the above four challenges, FpgaNIC adopts a layered design to enable easy design space exploration for SmartNIC architectures dedicated for various distributed applications that run on distributed GPUs, while minimizing the development effort and increasing the overall system efficiency. FpgaNIC consists of three main components: *GPU communication stack*, *reliable network transport in hardware*, and *on-NIC computing* (ONC), as shown in Figure 1. The goal of the GPU communication stack is 1) to allow the FPGA to use GPU virtual address (C1) to directly access GPU memory via direct PCIe P2P data communication at low-latency and line-rate, and 2) to allow GPUs to initiate data transfers by using *doorbell registers* on the FPGA to avoid having to involve the host CPU in the invocation. The goal of reliable network transport in hardware is to provide a reliable, low-latency, and high-throughput network access to the local GPUs (C2). The goal of on-NIC computing is 1) to enable high-level programming interface, and 2) to enable three NIC models: direct, on-path, and off-path, such that FpgaNIC is able to benefit a broad range of GPU-powered distributed applications (C4).

2.3 GPU Communication Stack

Built on a PCIe IP core, e.g., Xilinx’s UltraScale+ Gen3 x16, the GPU communication stack of FpgaNIC aims at enabling offloading the control plane onto GPUs (via a slave interface) and offloading the data plane onto the FPGA (via a master interface), such that the host CPU is bypassed.

2.3.1 Offloading Control Plane onto GPUs

In order to allow GPUs to directly access the FPGA’s control and status registers, FpgaNIC needs to offload the control plane onto the GPUs.

How to Enable Control Plane Offloading? Enabling control plane offloading requires a hardware-software codesign approach. On the hardware side, we enable a PCIe BAR exposing a configurable FPGA address space at the PCIe IP core on the FPGA. On the software side, our implementation consists of a *GPU driver*, an *FPGA driver*, and *user code* that interacts with both drivers. The process consists of three steps. First, the FPGA driver uses the function *misc_register* to register the PCIe BAR with the Linux kernel as an IO device */dev/fpga_control*. Second, the user code uses the function *mmap* to map the device into the host address. Third, the user code adopts a CUDA (Compute Unified Device Architecture) memory management function to register the host address for use within a CUDA kernel [52]. With this, the GPU can directly trigger doorbell registers and poll status registers on the FPGA without CPU intervention.

What Control Plane Offloading can Do? After enabling control plane offloading, the doorbell/status registers that are instantiated by all the components (GPU communications stack, ONC, and network transport) have to be mapped into

GPU virtual address space so that the GPU program is able to access these registers without CPU intervention. Moreover, it enables us to populate GPU TLB (GTLB) entries on the FPGA such that the FPGA can translate GPU virtual address to physical address before issuing a DMA read/write operation to GPU memory (§2.3.2).

2.3.2 Offloading Data Plane onto the FPGA

FpgaNIC needs to offload the data plane onto the FPGA to allow the FPGA to directly access the GPU memory. However, NVIDIA GPUDirect [52] allows direct PCIe P2P data communication using physical address. For the sake of easy programming, FpgaNIC needs to work on GPU virtual address, rather than physical address (C1). Via a GPU BAR window, Tesla GPUs expose all of their device memory space, e.g., 40GB, while Quadro GPUs typically expose 256MB memory space with 36MB reserved for internal use [52]. In order to allow the FPGA to access more GPU memory space, FpgaNIC needs to store all the related virtual to physical address translation entries. To minimize the overhead of translation, we intend to keep all the entries on on-chip memory. However, the 64KB GPU page size becomes the main challenge, because storing a great number of translation entries on the FPGA needs a large on-chip memory. For example, 32GB GPU memory needs 512K entries, far beyond the number the FPGA implementation can accommodate without hurting timing.

How to Enable FPGA to Efficiently Work on Virtual Address? To this end, we propose a GPU Translation Lookaside Buffer (GTLB) to perform address translation on the FPGA, while keeping the on-chip memory consumption reasonably low. The key motivation behind the design of GTLB is that even though a single contiguous virtual address space needs not be physically contiguous on GPU memory, it has high probability to be physically contiguous, especially at the granularity of 2MB. Therefore, we manually coalesce 32 consecutive 64KB GPU memory pages into a 2MB page if these 64KB pages are allocated to a contiguous portion of physical memory and aligned within the 2MB page. The GTLB consists of a *main TLB* and a *complementary TLB*. The process of populating the GTLB on the FPGA involves four steps, as shown in Algorithm 1. First, we pre-alloc GPU memory space using *gpuMemAlloc* for staging the GPU memory that will be accessed by the DMA engines on the FPGA (Line 1). Second, we pass the initial virtual address and length of this GPU memory to the GPU kernel function *nvidia_p2p_put_pages* to get all the $\langle VA, PA \rangle$ pairs for all the 64KB pages (Line 2), where VA refers to virtual address and PA refers to physical address. Third, we try to coalesce 64KB pages into 2M pages as aggressive as possible (Line 3). Fourth, we populate main and complementary TLBs (Lines 4-18) via the control registers exposed by the control plane offloading (§2.3.1). The main TLB provides the virtual to physical address translations for 2MB pages (Lines 7-10). If any 2MB page is not physi-

Algorithm 1: POPULATING GTLB

```
Input   : init_addr: initial GPU virtual address
          : len: length of GPU memory
Output  :  $TLB^{main}$ : main TLB
          :  $TLB^{comp}$ : complementary TLB
/* Step 1: Malloc GPU memory space. */
1 init_addr = gpuMemAlloc(len);
/* Step 2: Get <VA, PA> pairs of all the 64KB pages. */
2 <VA64KB, PA64KB> pairs = nvidia_p2p_put_pages(init_addr, len);
/* Step 3: Coalescing 64KB pages to 2MB pages if possible */
3 <VA2MB, PA2MB> pairs ← <VA64KB, PA64KB> pairs;
/* Step 4: Populating  $TLB^{main}$  and  $TLB^{comp}$  */
4 index = 0; /* Large page index */
5 comp = 0; /* Base page index */
6 for (pair in <VA2MB, PA2MB> pairs) do
7   if (pair is physically contiguous) then
8     /* Update the  $TLB^{main}$  */
9      $TLB^{main}[index].pair$  = pair;
10     $TLB^{main}[index].valid$  = 1;
11   end
12   else
13     /* Update the  $TLB^{comp}$  */
14      $TLB^{comp}[32 * comp + 31 : 32 * comp]$  = pair's 32 64KB pages;
15      $TLB^{main}[index].valid$  = 0;
16      $TLB^{main}[index].comp\_offset$  = comp*32;
17     comp++;
18   end
19 index++;
end
```

cally contiguous, we store the corresponding 32 translations of 32 64KB pages in the complementary TLB, which provides 2048 entires for accommodating 64 such 2M pages (Lines 12-15).⁵ As such, the total number of required entires for 32GB memory becomes 16K+2K=18K, significantly smaller than the previous 512K entries.

Fully-pipelined Translation Lookup. After the population, FpgaNIC is able to directly access GPU memory using on-line virtual to physical address translation. Given a virtual address, FpgaNIC first checks the corresponding entry in the main TLB to see whether it is continuous or not ($TLB^{main}.valid == 1$). If yes, FpgaNIC fetches the PA and feeds it into the DMA engine. If no, FpgaNIC will read the corresponding entry in the complementary TLB using the offset $TLB^{main}.comp_offset$. We can observe that the proposed GTLB can easily achieve fully-pipelined translation lookup on the FPGA.

GTLB Miss/Eviction. Currently, we pre-populate TLB entries for each application, assuming that the FPGA only accesses certain range of GPU memory. When GTLB miss or eviction happens, we need to re-populate GTLB entries for successful GPU memory references. However, we suggest to instantiate multiple GTLBs to provide sufficient number of GTLB entries to eliminate potential GTLB misses and evictions on the FPGA, because each GTLB entry only occupies a row of a BRAM, indicating relatively low cost of storing GTLB entries on the FPGA.

⁵In our experiment, 2048 entires are far beyond enough.

2.4 100Gbps Hardware Network Transport

In order to address the second challenge (C2), FpgaNIC offloads the transport-layer network to the FPGA to provide a reliable and high-performance hardware network transport to the local GPUs. Fortunately, there is a growing amount of open-source FPGA-based 100Gb network stacks such as the TCP/IP stack of [57, 60] and the RoCEv2 stack used in [62]. Without loss of generality, FpgaNIC is built on the 100Gb TCP/IP stack [57, 60], which is able to support thousands of connections with external FPGA memory for buffering.⁶ We have modified this stack to adapt it to the requirements of FpgaNIC's by modifying its interface to improve bandwidth utilization and allow local GPUs to directly control the network transport.

2.4.1 Efficient Decoupled Application Interface

The original application interface [25, 57, 60] requires a control handshake between the TCP stack and the application code before sending or receiving a network packet to or from the TCP stack. A control handshake takes from 10 to 30 cycles while the payload of a packet (up to 1460B) only takes up to 23 cycles, leading to low network bandwidth utilization. To reduce the overhead of the handshake, we introduce an efficient decoupled application interface that does not need the handshake and further overlaps the control handshake and the packet transfer, maximizing the network bandwidth utilization and easing programming.

Decoupled Sending Application Interface. The original sending interface only allows to send a data chunk at a time after a control handshake, where the size of a data chunk is up to 1460B. A data chunk and a TCP header constitute a TCP segment, which can be encapsulated into an IP packet before sending over Ethernet. The proposed decoupled interface gets rid of the handshake, overlapping the control handshakes with the data transfer. And it further allows to send data streams of up to 4GB in size by automatically splitting the data stream into the right size chunks without programmer's involvement in packetization.

Decoupled Receiving Application Interface. The original receiving interface informs the user logic through a valid notification when a TCP segment is available to be consumed, which then sends out the read request to the receiving interface. After 10 to 30 cycles, the TCP segment's payload will be available at the 64B-wide AXI (Advanced eXtensible Interface)-Stream interface and consumed by the user logic. Similar to the sending interface, the proposed decoupled interface gets rid of the handshake, and further overlaps handshake

⁶The TCP stack needs two 64KB fixed-sized buffers per connection, one buffer for incoming packets and the other for outgoing packets. Therefore, external FPGA memory is needed to support thousands of concurrent connections. However, if fewer than 10 concurrent connections are needed, the TCP stack of [57, 60] can implement the buffers using on-chip memory such that external FPGA memory could be saved for offloaded smart functionality. In this paper, FpgaNIC uses both versions.

Table 2: Resource Usage breakdown of FpgaNIC on U50.

| | LUTs | REGs | RAMs | DSPs |
|-----------------------------|--------|--------|---------|------|
| Available | 871K | 1743K | 232.4Mb | 9024 |
| GPU Commu. Stack | 79K | 103K | 5.2Mb | 0 |
| 100G HW Transport | 101.3K | 166.5K | 23.4Mb | 0 |
| ONC: GPU-centric networking | 14.5K | 20K | 24.6Mb | 0 |
| ONC: AllReduce | 7.3K | 10K | 12.8Mb | 0 |
| ONC: Hyperloglog | 19.5K | 26K | 7.1Mb | 1104 |

and data transfer and assembles the complete data stream for each TCP connection without programmer’s involvement in depacketization.

2.5 On-NIC Computing (ONC)

The on-NIC computing module sits between the GPU communication stack module and the 100Gbps network hardware transport module, so ONC can directly manipulate the other two modules to enable flexible design space exploration around GPU-centric SmartNICs. The key goal of on-NIC computing module is to 1) expose high-level programming interface for system programmer, and 2) enable three SmartNIC models for various GPU-powered distributed applications. In the following, we discuss the programming interface of ONC and how to enable three three models.

2.5.1 High-level Manipulation Interfaces of ONC

In order to address the third challenge (C3), FpgaNIC intends to raises the programming abstraction from HDL to high-level synthesis (HLS), i.e., C/C++, such that systems programmers are able to use C/C++ to manipulate FpgaNIC, rather than cycle-sensitive HDL.⁷ In the following, we present the concrete manipulation interfaces for the GPU communication stack and hardware network transport modules.

Manipulation Interfaces of GPU Communication Stack. The GPU communication stack exposes two manipulation interfaces: a slave interface that allows GPUs to access FPGA’s registers and a master interface that allows the FPGA to directly access GPU memory, as shown in Table 3.

The slave interface is a 4B-wide AXI-Lite interface (*axilite_control*), through which local GPUs directly access doorbell and status registers within FpgaNIC without CPU intervention. In FpgaNIC, we instantiate 512 doorbell registers and 512 status registers, each of which has its own PCIe address to allow individual access. We correspond a few doorbell and status registers to each *engine* from any of three components within FpgaNIC. The doorbell registers can be triggered by GPUs to manipulate the engine, and the status registers can be polled by GPUs to check the status of the engine.

The master interface consists of two command streams and two data streams. The two command streams are 96-bit-wide AXI-Stream interfaces (*dma_read_cmd* and *dma_write_cmd*) that provide the GPU virtual address and length to directly access GPU memory, where the length is

⁷Nevertheless, ONC can be also programmed in HDL if necessary.

Table 3: Two interfaces of GPU communication stack

| Type | Interface | Content |
|------------------|------------------------|--------------------------------------|
| Slave interface | <i>axilite_control</i> | AXI-Lite interface for configuration |
| Master interface | <i>dma_read_cmd</i> | Dest. GPU virtual address, length |
| | <i>dma_read_data</i> | AXI data stream from GPU memory |
| | <i>dma_write_cmd</i> | Source GPU virtual address, length |
| | <i>dma_write_data</i> | AXI data stream to GPU memory |

Table 4: Manipulation interface for the network transport

| Type | Interface | Meaning |
|-------------------|----------------------------|------------------------------------|
| Data interface | <i>tcp_tx_meta</i> | Session ID, length |
| | <i>tcp_tx_data</i> | AXI data stream to remote node |
| | <i>tcp_rx_meta</i> | Session ID, length, IP, port, etc. |
| | <i>tcp_rx_data</i> | AXI data stream from remote node |
| Control interface | <i>server_listen_port</i> | A TCP listening port |
| | <i>server_listen_start</i> | Starting to listen |
| | <i>client_conn_port</i> | Destination port to connect |
| | <i>client_conn_ip</i> | Destination ip to connect |
| | <i>client_conn_start</i> | Start to connect to server |
| | <i>conn_close_session</i> | Destination session to connect |
| | <i>conn_close_start</i> | Start to close connection |

up to 4G. The data from and to GPU memory is sent over the *dma_read_data* and *dma_write_data* data streams, which are 64B-wide AXI-Stream interfaces. For either GPU memory read or write operation, we need to configure the command stream and then work on the corresponding data stream, allowing programmers to easily access GPU memory.

Interfaces of Hardware Network Transport. The hardware network transport exposes two interfaces: *data interface* and *control interface*.

The data interface consists of a *sending interface* and a *receiving interface*. The sending interface consists of a metadata stream and a data stream. The metadata stream (*tcp_tx_meta*) is a 48-bit-wide AXI-Stream that provides a 4B-wide data length and a 2B-wide session ID that corresponds to a remote node. The data stream (*tcp_tx_data*) is a 64B-wide AXI-Stream to send payload stream. The receiving interface also consists of a metadata stream and a data stream. The metadata stream (*tcp_rx_meta*) is an 44B-wide AXI-Stream that provides session ID, length, IP address, port and close session flag. The data stream (*tcp_rx_data*) is a 64B-wide AXI-Stream to receive payload stream from remote node.

The control interface of the hardware transport is similar to that of the well-understood socket interface, which allows GPU programmers to easily leverage the network transport, with their meanings as shown in Table 4. We instantiate the corresponding doorbell and status registers, exposed through the PCIe’s slave interface (§2.3), to allow local GPUs to directly manipulate or poll the 100Gb hardware network transport.⁸ In summary, the network transport serves as a network proxy, through which the ONC module and local GPUs can access the network transport directly without CPU intervention, so as to address the second challenge C2.

⁸Inside the FPGA, the ONC module (§2.5) can also directly manipulate the hardware transport via these registers.

Table 5: Lines of code for each component of FpgaNIC

| | Hardware | Software |
|-----------------------------|--------------------|------------------|
| GPU Commu. Stack | 2.9K (Verilog/HLS) | 0.7K (C++, CUDA) |
| 100G HW Transport | 15.3K (HLS) | |
| ONC: GPU-centric networking | 1.0K (HLS) | 0.5K (C++, CUDA) |
| ONC: AllReduce | 2.7K (HLS/Verilog) | 1.5K (C++) |
| ONC: Hyperloglog | 1.6K (HLS) | 0.3K (C++, CUDA) |

2.5.2 How to Support Three SmartNIC Models?

In order to address the fourth challenge **C4**, FpgaNIC’s on-NIC computing component allows system programmers to customize data-path engines between the GPU communication stack and the hardware network transport to accelerate various distributed applications. Table 2 shows that the previous GPU communication stack and network transport consume less than 20% FPGA resources on a mid-sized FPGA U50, so the on-NIC computing component has plenty of resources to realize complex data-path engines to accelerate various distributed applications. Moreover, the commercial FPGA board that features DDR4 (even HBM) is able to stage data from network or GPUs, and perform on-NIC computing on the data before feeding into GPUs or sending out to network.

Due to the reconfigurable nature of the FPGA, FpgaNIC can easily support various SmartNIC models: direct, on-path, and off-path, to benefit a broad range of distributed applications. Table 5 shows the lines of code for each component.

The direct model directly exposes the hardware network transport module to local GPUs via the GPU communication stack module, such that local GPUs can directly manipulate the network transport to do reliable network communication. An example, we develop a GPU-centric networking to demonstrate the potentials of the direct model. Due to space limitation, we describe the detailed design and implementation of GPU-centric networking to the Appendix §A.1.

The on-path model is similar to the direct model that local GPUs directly manipulate the hardware network transport, except that the on-path model allows the network stream also to enter an on-path engine in the ONC component for the offloaded computation, where the on-path engine needs to consume the network stream at line-rate such that the on-path engine would not impede line-rate network traffic. We use the HyperLogLog (HLL) application [18, 33] as an example to demonstrate the power of the on-path model. The detailed design and implementation of HLL with FpgaNIC can be found in the Appendix §A.3.

The off-path model enables an off-path engine in the ONC component to directly manipulate the GPU communication stack and the hardware network transport such that FpgaNIC is able to orchestrate the data flow between all the three components. Typically, the off-path needs to stage data in on-board memory. We use the collective communication primitive AllReduce [4, 11, 50] as an example to demonstrate the power of the off-path model (§A.2). The detailed design and

Figure 2: Experimental Setup

implementation of AllReduce with FpgaNIC is in the Appendix §A.2.⁹

How to Support Multiple Tenants? To support multiple tenants, we can adopt Coyote [32] to wire the GPU communication stack and hardware network stack into the static region of FpgaNIC while exposing the same programming interface to offloaded tasks, for which we pre-synthesize the FPGA bitstreams ahead of time. Furthermore, FpgaNIC adopts the notion of *vFPGAs* (virtual FPGAs or separate application regions that are individually reconfigurable) as implemented in Coyote [32] to smoothly support secure, temporal and spatial multiplexing of GPU communication stack and hardware network transport between tenants (without pre-emption and context switching). For each tenant, FpgaNIC provides sufficient FPGA resources in a partial reconfiguration region to implement an independent ONC engine to guarantee performance isolation, and thus we no longer need to reboot the FPGA to change the functionality of FpgaNIC. We leave this as future work.

3 Experimental Evaluation

3.1 Experimental Setup

System Architecture. The experiments are run on a cluster consisting of eight 4U AMAX servers, connected with a Mellanox 100Gbps Ethernet SN2700 switch (Figure 2). Each server is equipped with two Intel Xeon Silver 4214 CPUs @2.20GHz, 128GB memory, FpgaNIC (i.e., a Xilinx Ultra-Scale+ FPGA [72]), and a Nvidia RTX 8000 GPU, where the FPGA and the GPU have direct PCIe P2P communication, as shown in Figure 1. Two servers have an additional two A100 GPUs. FpgaNIC is implemented on Xilinx Alveo cards U50 or U280 with Vivado 2020.1.

Methodology. We first benchmark the GPU communication stack and hardware network transport to demonstrate that FpgaNIC allows easy PCIe P2P communication with local GPUs and reliable network communication with remote GPUs. We then evaluate the three FpgaNIC models: direct (§3.3), off-path (§3.4), and on-path (§3.5), to demonstrate FpgaNIC’s performance and ability to enable the exploration of a large SmartNIC design space.

⁹The off-path model is generic enough such that it would also work well in other applications that follow a partition/aggregate pattern and require multiple rounds of communication [38].

3.2 Benchmarking Shared Infrastructure

We benchmark the shared GPU communication stack and hardware network transport.

3.2.1 GPU Communication Stack

To analyze the effect of control plane and data plane offloading, we measure the latency and throughput of the PCIe P2P link (§2.3). We use two classes of GPU: Quadro RTX8000 (labelled “R8K”) and Tesla A100 (labelled “A100”), since a different GPU class leads to different latency and throughput.

Effect of Control Plane Offloading. We examine the effect of control plane offloading by comparing the latency of commands issued from the GPU to the FPGA. Figure 3 shows the read latency when using various end points: “X_Y” means that device “X” reads from device “Y”. A first important result is that the latency of interactions between the GPU and the FPGA is comparable to that of the CPU calling the FPGA and it is under 1 microsecond. Moreover, the GPU-FPGA’s latency fluctuation is smaller than that of CPU-FPGA, demonstrating one of the advantages of FpgaNIC in terms of offering deterministic latency. The results also show that performance improves slightly with a better GPU, indicating that the overall system will improve with future versions of the GPU. Finally, the latency of “GPU_FPGA” is significantly lower than that of “GPU_CPU” plus “CPU_FPGA”, proving the efficiency of control plane offloading proposed in FpgaNIC.

Figure 3: Control plane latency comparison. X_Y refers to the device “X” accesses the device “Y”. R8K refers to RTX 8000 GPU, and A100 refers to A100 GPU. Whiskers show the 1st and 99th percentile.

Effect of Data Plane Offloading. We examine the effect of data plane offloading by measuring the throughput when the FPGA issues a DMA read/write operation to GPUs. Each operation transfers 4GB of data between the FPGA and the GPU memory. Figure 4 illustrates the achievable throughput with varying burst size, which is associated with the length of a DMA operation. It is interesting to observe that DMA read and write operations reach peak throughput at different burst sizes: 512B for read and 8K for write, indicating that we need to carefully choose the right DMA size to saturate the PCIe P2P bandwidth between FPGA and GPU. As with latency, a newer GPU class leads to much higher PCIe throughput. For example, a DMA read operation to an A100 GPU yields 12.6GB/s, close to the maximum possible PCIe bandwidth.

Figure 4: PCIe P2P throughput between FPGA and GPU

3.2.2 Hardware Network Transport

Next, we measure the throughput and latency of the hardware network transport (§2.4).

Latency. We measure the round-trip time (RTT) between two FPGAs connected via the network switch. Figure 5a shows the RTT with varying message size. The most striking result is that the TCP latency is in microseconds, instead of milliseconds, demonstrating the advantages of offloading to a SmartNIC instead of using the CPU for communication. For messages smaller than 1 KB, the RTT latency (roughly 3.1us) is dominated by the physical communication path (the Ethernet switch introduces an additional hop with roughly 1us latency).

Throughput. We measure as well the throughput between two network transports with varying packet size and varying number of connections. Figure 5b shows the observed throughput by sending out a total of 1GB from one transport to the other with varying packet size and number of connections. We observe that the number of connections does not affect the achievable throughput under the same packet size, indicating that FpgaNIC is able to efficiently support multi-connection communication. For small packets, the throughput is low due to the fixed overhead, i.e., the 40B header, per packet and the turnaround cycles to process each packet. However, for larger packets, the achievable throughput is close to the 100Gbps channel capacity, demonstrating that FpgaNIC efficiently uses the available network bandwidth.

3.3 Evaluation of the Direct Model

We evaluate the throughput of FpgaNIC used in direct mode. The experiment involves sending data from one GPU to a remote GPU through the corresponding FPGAs using the direct model path: GPU-PCIe-FPGA-network-FPGA-PCIe-GPU.

Effect of Slot Size. We examine the effect of the slot size (W) of the circular buffer for each connection (§A.1.2). The slot size determines the size of the DMA operation between an FPGA and a GPU. Figure 6a illustrates the throughput with varying slot size. We have two observations. First, a sufficiently large slot size leads to saturated throughput. A

(a) Round-trip latency with varying message size

(b) Throughput with varying packet size and connections

Figure 5: 100Gb TCP stack: latency and throughput

small slot size (<64KB) leads to lower throughput since it leads to low DMA engine utilization (Figure 4). Second, the network bandwidth between A100 GPUs is higher than that between RTX 8000 GPUs, as the slow PCIe speed between a RTX 8000 GPU and the FPGA becomes the bottleneck of network bandwidth (Figure 4).

Effect of Control Plane Offloading on Slot Size. We examine the effect of control plane offloading on different slot sizes. Without control plane offloading, we need to use CPU to trigger the DMA operation after executing a CUDA kernel that copies a chunk in the “GPU user” layer into the *send buffer* in the “GPU kernel” layer, leading to one kernel invocation per chunk. Intuitively, such frequent kernel invocations lead to significant overhead when the chunk size or the transfer size is not large. Figure 6b illustrates the throughput comparison with and without control plane offloading under different chunk size, when the data transfer size is 1GB. We observe that control plane offloading can lead to obviously higher throughput than the implementation without control plane offloading. Moreover, a smaller chunk size leads to higher throughput improvement, because control plane offloading eliminates more CUDA kernel invocations.

Effect of Control Plane Offloading on Transfer Size. We examine the effect of control plane offloading on different transfer sizes. Figure 6c illustrates the throughput comparison with and without control plane offloading under different transfer size, when the chunk size is 64KB. We observe that when the transfer length is smaller, control plane offloading leads to significant throughput improvement over the case without control plane offloading, whose performance is domi-

(a) Effect of DMA size with control plane offloading

(b) Effect of control plane offloading on chunk size

(c) Effect of control plane offloading on transfer size

Figure 6: Throughput of GPU-centric networking

nated by the kernel invocation overhead and context switch. In contrast, control plane offloading can remove these overheads by triggering doorbell registers from within a CUDA kernel, rather other from the host CPU.

3.4 Evaluation of the Off-path Model

In this subsection, we evaluate the performance of FpgaNIC-enhanced AllReduce on a distributed pool of eight GPUs, as shown in Figure 2. When accelerating AllReduce, we configure FpgaNIC in an off-path model and offload the AllReduce engine to the FPGA. In the following, we present the baseline and the corresponding performance comparison.

Baseline. The experimental platform used as a baseline is similar to Figure 2, except that FpgaNIC in each server is replaced with a Mellanox ConnectX-5 100Gbps MT27800 NIC with RoCE and GPUDirect enabled. We use NVIDIA Collective Communication Library (NCCL) [50] which provides state-of-the-art collective communication primitives, e.g., AllReduce, over distributed Nvidia GPUs.

Figure 7: Effect of data size under eight nodes

Figure 8: Effect of node number with 64MB data size

Comparison Metric. To demonstrate the performance of AllReduce, we introduce the metric *bus bandwidth* [51], which is calculated to be *algorithm bandwidth* times $2 * (N - 1) / N$, where *algorithm bandwidth* is calculated to be the data size divided by the elapsed time and N is the number of nodes. The elapsed time is estimated to be the average time of all the involved nodes in five rounds [9].

Effect of Data Size. We examine the effect of data size when performing AllReduce. Intuitively, a large data size easily leads to a saturated throughput because we hit the bandwidth limits of the underlying channels. Figure 7 illustrates the bus bandwidth comparison between FpgaNIC and NCCL in a cluster with 8 nodes. FpgaNIC leads to up to 2.5x speedup over NCCL, because the AllReduce engine in FpgaNIC efficiently overlaps the operations of the PCIe DMA, network transport, and FPGA memory. Moreover, FpgaNIC does not consume any GPU/CPU cycles, freeing up these precious computing resources for other important tasks. FpgaNIC reaches the theoretical bus bandwidth when the data size is larger than 8MB, indicating that FpgaNIC’s AllReduce implementation is using all resources efficiently. Finally, when data size is small (<1MB), the speedup is up to 2.5x, due to the faster transition between states in FpgaNIC (Table 8) when compared to the same operation being implemented on GPUs.

Impact of Systems Size. We examine the effect of number of nodes on the AllReduce performance under 64MB data size. Figure 8 shows how both FpgaNIC and NCCL reach the theoretical bus bandwidth with an increasing number of nodes. However, NCCL needs a quite amount of CPU/GPU computing cycles to realize, while FpgaNIC does not.

Discussion. In the context of distributed AI model training, these results indicate that only offloading the AllReduce engine will not be able to fully harvest FpgaNIC’s potential. We can offload not only the communication functions (i.e., the

AllReduce engine) but also part of the learning engine such as the compressor (e.g., compression engine) and optimizer (e.g., Adam engine) to FpgaNIC, such that the entire communication part of training is offloaded to minimize the communication overhead for GPUs. Since these engines can easily achieve line-rate throughput, plenty of interesting trade-offs in the design of distributed learning, e.g., sync vs. async, can be revisited by using FpgaNIC. We leave this idea to future work.

3.5 Evaluation of the On-path Model

We finally evaluate the performance of FpgaNIC-enhanced HLL, when FpgaNIC is configured in an on-path model. The cardinality is calculated when the data stream has been transferred. The goal of this experiment is to verify whether the HLL module within an FPGA can act as a bump in the wire.

The baseline, labelled “write”, is to feed data to a GPU without processing the data in the FPGA. The GPU receives the data from the FPGA and stores it in the current *block* in GPU memory, while at the same time performing HLL on the previous block, overlapping data transfer with cardinality calculation at the block granularity. Table 6 illustrates that at least 8 SMs, in terms of 8 thread blocks and 512 threads per a thread block, are required to consume 100Gbps data stream (packet payload size: 1408 bytes) on an A100 GPU, when the block size is no smaller than 256K. Moreover, when the block size is smaller than 128K, an A100 GPU is not able to consume the data stream, as such a small block size cannot fully utilize GPU’s processing parallelism.

Table 6: Number of required GPU SMs w.r.t block size

| Block size | <=128K | 256K | 512K | 1024K |
|--------------------|--------|------|------|-------|
| Number of A100 SMs | >256 | 8 | 8 | 8 |

Figure 9: Performance of HLL with and without offloading. HLL with offloading does not affect the overall throughput, but saves at least 8 A100 GPU SMs, required by HLL without offloading, to consume 100 Gbps HLL data stream.

Figure 9 illustrates that FpgaNIC-enhanced HLL is able to achieve similar throughput as the baseline under various packet payload size, where the block size is 256K. It indicates that offloading HLL does not block the incoming data stream and introduces negligible latency. More important, FpgaNIC-enhanced HLL does not require any GPU compute power,

Table 7: Comparison of FpgaNIC with existing SmartNICs from industry. ✓ indicates full support, ✗ indicates no support.

| | Programmable flow processing | Targeted applications | CPU-centric | GPU-centric |
|-------------------|------------------------------|--|-------------|-------------|
| Broadcom [7] | ✓ | Virtualization, storage, NFV | ✓ | ✗ |
| Pensando [53] | ✓ | Storage, security | ✓ | ✗ |
| Netronome [49] | ✓ | SDN-controlled server-based networking | ✓ | ✗ |
| Intel IPU [23,24] | ✓ | Cloud, storage, security | ✓ | ✗ |
| FpgaNIC | ✓ | AI model training | ✗ | ✓ |

e.g., at least 8 A100 SMs, which can be used in other computing task. Moreover, Table 2 shows that FpgaNIC-enhanced HLL takes a small amount of FPGA resources. Therefore, in the context of FPGA+GPU co-processing, it is clearly more efficient to offload HLL onto FpgaNIC, rather than processing HLL on the GPU.

4 Related Work

To our knowledge, FpgaNIC is the first FPGA-based GPU-centric 100Gbps SmartNIC that addresses the bottleneck limitations introduced by the use of conventional CPUs or small cores (ARM) in SmartNICs.

FPGA-augmented SmartNICs. Several commercial systems [10, 21, 22, 45, 55, 79] feature an FPGA within a SmartNIC. The closest work is from Mellanox Innova [45] that features an FPGA in its SmartNIC to accelerate offloaded compute-intensive applications, while PCIe and network interfaces are handled by a NIC ASIC ConnectX-5. The FPGA is connected with the NIC ASIC via a PCIe interface and therefore acts as an additional PCIe endpoint. The FPGA is entirely dedicated to the user’s application logic. In contrast, FpgaNIC implements all functionalities, including networking and PCIe, within a powerful FPGA, enabling a large design space exploration of SmartNIC architecture, while Innova provides limited architectural flexibility due to how the FPGA is connected.

GPU-FPGA Communication. Previous work [6, 64] has implemented GPUDirect RDMA on an FPGA to directly access GPU memory, but not allowing the GPU to trigger doorbell registers within an FPGA. In contrast, FpgaNIC allows GPUDirect RDMA and the GPU to trigger registers within an FPGA, and is an FPGA-based SmartNIC that allows large design space exploration of SmartNIC architecture.

Acceleration using FPGA-based SmartNICs. Most previous work [2, 3, 8, 10, 13, 14, 14, 17, 26, 35, 36, 36, 37, 59, 62, 65] features an FPGA on SmartNICs to offload data processing to the network from the host CPU. In contrast, FpgaNIC is an FPGA-based full-stack SmartNIC that mainly targets compute task offloading from local GPUs which require a more complex system than offloading for CPUs. For example, we can offload partial G-TADOC [76, 77] that is a novel optimization to perform compressed data direct processing onto FpgaNIC to maximize the performance of distributed system under efficient FPGA-GPU co-processing.

Multicore-based SmartNICs. There is also a lot of work

done [12, 16, 29, 41, 42, 44, 47, 48, 54, 56, 63, 66, 70] on SmartNIC built upon a wimpy RISC cores plus hardware engines to accelerate dedicated functionality such as compression. These RISC cores are used to both process packets as well as to implement “smart” functions instead of using the host CPUs. Such an approach inevitably suffers from load interference since packet processing and the smart functions have to compete for the shared resources, e.g., the last level cache and memory bandwidth. In contrast, FpgaNIC implements an GPU-centric SmartNIC on an FPGA.

On-going SmartNICs in Industry. Besides NVIDIA’s DPU, we compare FpgaNIC with other SmartNICs from industry, as shown in Table 7. Broadcom offers the Stingray SmartNIC [7], which features a ARM 8-core CPU for control-plane management and P4-like TruFlow packet processing engine for data-plane processing, targeting various applications such as virtualization, storage, and NFV. Pensando has a DPU architecture [53] that features an ARM CPU and a P4 processor for data-plane packet processing, targeting various applications such as security and storage. Netronome provides the NFP4000 Flow Processor architecture [49] that features a ARM CPU, 48 packet processing cores, and 60 P4-programmable flow processing cores for data-plane processing, targeting the SDN-controlled server-based networking application. Intel presents the FPGA-based IPU (Infrastructure Processing Unit) that consists of a MAX 10 FPGA for control-plane management and an Arria 10 FPGA for data-plane processing [23], and uses an ASIC IPU whose architecture is not publicly documented [24]. Fungible has a DPU [15] featuring multiple PCIe endpoints, TrueFabric for networking, and specialized engines such as compression and EC/RAID to address inefficient data-centric computation within a node and inefficient interchange between nodes, targeting various applications such as virtualization, cloud storage, and data analytics. All these systems are CPU-centric in that they are designed to complement the CPU. In several cases, they suffer from the bottleneck problem pointed out above that prevents them from being able to operate at line rate. In contrast, FpgaNIC is an FPGA-based GPU-centric SmartNIC that targets various applications such as AI model training and security and specifically designed to operate at line rate which also means that it might not be suitable for operations that would significantly impair the flow of network packets (such as blocking operations or computations generating large amounts of intermediate state).

5 Insights and Implications of FpgaNIC

In this section, we discuss three interesting properties regarding FpgaNIC.

High Performance of On-NIC Computing Module. An increasing amount of SmartNIC solutions intend to remove the conventional CPU from the data-path (e.g., Microsoft Catapult). However, they either do not exploit the possibilities of direct communication between the FPGA and the GPU, or use small CPUs (ARM cores) that cannot process at line rate to impose additional hops within the NIC to implement the smart functionality (e.g., Bluefield-2). Furthermore, commercially available multi-core SmartNICs, such as BlueField-2, fail to process 100Gbps network traffic at line rate with its embedded CPU, which is capable of doing control-plane management only. The embedded CPU in Bluefield-2 is overwhelmed by trying to stage a 100Gbps data stream coming from the network. In contrast, FpgaNIC provides a 100Gbps data-path accelerator for distributed computing over GPUs, and thus enables a large design space exploration around SmartNIC for GPU-based applications. The key aspect of FpgaNIC is that it can process data at line rate as it comes from the network, something that other systems cannot do, because this requires to insert the accelerator in the data path, which cannot be done with conventional hardware (running conventional software) but can be done with FPGAs. To do so, FpgaNIC only consumes roughly 20% of the FPGA resources (marked in blue) to implement the NIC architecture (100Gbps hardware network transport and GPU communication stack) in a half-length, half-height FPGA board (Alveo U50), as shown in Table 5. It implies that the majority of the FPGA resources can be dedicated to on-NIC computing for SmartNIC functionality. Moreover, U50 has High Bandwidth Memory (HBM) which can be used to implement functionality with more intermediate states as memory access does not become the bottleneck. Therefore, FpgaNIC allows the offloading of compute-bound and memory-intensive tasks from multiple tenants (e.g., like in [39]) onto a mid-size FPGA.

Performance Guarantee and Isolation. Many multicore-based SmartNICs use small CPU cores for in-network computing. On these CPUs is really hard to provide performance guarantee and isolation due to insufficient CPU processing abilities and interference across tasks. We have shown that FpgaNIC is able to guarantee performance and isolation from two perspectives. From a compute's perspective, FpgaNIC provides dedicated hardware resources for each offloaded compute task, leading to a strict performance guarantee and perfect performance isolation. From a memory's perspective, U50 features 2-channel HBMs [71, 75] with 32 independent memory channels, each of which provides up to 13.6GB/s of memory throughput [20, 68]. This guarantees that each offloaded compute task is able to gain exclusive control over the assigned memory channels, without interfering with other offloaded compute tasks and the NIC infrastructure, which op-

erates on dedicated hardware resources to guarantee line-rate network throughput.

Medium Programmability. Programming FPGAs using a Hardware Description Language (HDL), is error-prone and difficult to debug, limiting the adoption of FPGAs by system programmers. When using FpgaNIC, we intentionally ensure that it can be programmed using C++-based HLS (High Level Synthesis), to make it easier to use for software programmers, where HLS is the highest level of abstraction commercially available for programming FPGAs. To let FpgaNIC support both HDL and HLS, FpgaNIC's interface mainly leverages the stream type in HLS, i.e., AXI stream in HDL, for better compatibility. In future work, we intend to raise the level of abstraction further by developing a comprehensive framework such that users without hardware design experience can easily leverage FpgaNIC to accelerate distributed GPU-powered applications by automatically identifying offloaded functionalities via an FPGA-aware performance analysis framework [69] for maximum performance and high programmability.

6 Conclusion

Inspired by the fact that there is no SmartNIC designed for GPUs, we present FpgaNIC, a full-stack FPGA-based GPU-centric 100Gbps SmartNIC that allows a large design space exploration around SmartNICs for accelerating applications running on distributed GPUs. FpgaNIC enables direct data communication to local GPUs via PCIe P2P communication, enables local GPUs to directly manipulate the FPGA, provides reliable network communication with remote nodes, and enables on-NIC computing module to process the data from network at line rate. FpgaNIC can be efficiently used in three SmartNIC modes: direct, off-path, and on-path, to accelerate a broad range of GPU-powered distributed applications, such as Deep Learning model training. FpgaNIC is open-source to encourage further development and research in GPU-centric applications (Github: <https://github.com/RC4ML/FpgaNIC>).

Acknowledgement. We thank our shepherd and anonymous reviewers for their constructive suggestions. We are grateful to the AMD-Xilinx University Program for the donation of some of the AMD-Xilinx FPGAs used in the experiments. The work is supported by the following grants: the National Key R&D Program of China (Grant No. 2020AAA0103800), the Fundamental Research Funds for the Central Universities 226-2022-00151 and 226-2022-00051, Starry Night Science Fund of Zhejiang University Shanghai Institute for Advanced Study (SN-ZJU-SIAS-0010).

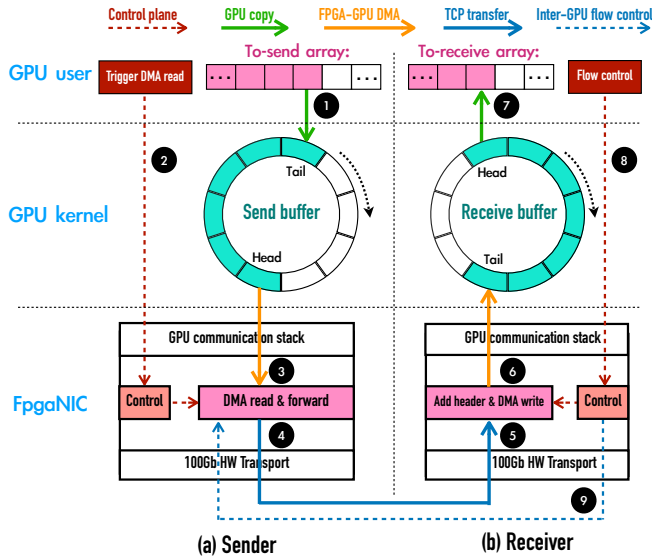

Figure 11: GCN between a sender and a receiver

GPU Kernel Layer. To manage incoming and outgoing traffic, we implement a *send buffer* and a *receive buffer*, conceptually two circular buffers, for each established connection. The key role of either buffer is to provide a staging option at the GPU memory exposed to other PCIe devices, as not all the memory space is visible to other PCIe devices on Quadro GPUs. Since the total exposed memory size is 220MB, we allocate 100MB to the send buffers and 100MB to the receive buffers, while the remaining 20MB is reserved for internal use. The number of supported connections is N , so each connection has a circular buffer of size $M = 100/N$ MB. We also split a circular buffer into F slots, each of which containing $W = \frac{M}{F}$ MB GPU memory space.¹¹

GPU User Layer. In the GPU user layer, calling a `send()` or a `receive()` function will launch a *data-mover* kernel that leverages Streaming Multiprocessing (SM)¹² to move data between the GPU user and kernel layers such that the speed of the data mover matches the DMA read/write speed.

A.1.3 Handshake Protocol of GCN

We demonstrate how the handshake protocol works in GCN. The key idea is to directly leverage the TCP stack on the FPGA (§2.4) via the control plane offloaded to GPUs. The handshake process consists of the following three steps.

First, each side creates a GPU-aware context by calling `create_socket_context`, which specifies the number N of supported TCP connections (e.g., 8), the GPU send/recv buffer size of each connection (e.g., 12.5MB), the initial address of control plane.

¹¹Nevertheless, FpgaNIC can be easily extended to support dynamic buffer size with slight modifications in the GPU kernel layer.

¹²In our experiment, a Streaming Multiprocessing (SM) provides more than enough throughput on both Quadro and Tesla GPUs. Each SM consists of 64 GPU cores. RTX8000 has 72 SMs while A100 has 108.

Second, each side creates a socket (`sockfd`) using the function `socket`, which launches a GPU kernel with only one thread that will apply for one free TCP connection slot in the FPGA 100Gb TCP stack.

Third, the server will listen to the socket `sockfd` by setting the listen-port register `listen_port` and then triggering the doorbell register `listen_start` (Table 4). Then, the server initiates the function `accept` to wait for an incoming connection from a client. The client calls the function `connect` with two parameters `conn_port` and `conn_ip` to specify the destination IP address and port. Once a connection is established, a client and a server can proceed to exchange data.

A.1.4 Send/Recv Functions of GCN

We now describe the implementation details of the two-sided communication between distributed GPUs by explaining the overall data and control flow shown in Figure 11.

Data Flow. The sender splits the “to-send array” into chunks, each of which has the size of W MB. For each chunk, we perform the following five steps. First, we employ a data-mover kernel that occupies a GPU SM, in terms of a thread block with 1024 threads, to copy a chunk in the “GPU user” layer into the “tail” slot in the *send buffer* in the “GPU kernel” layer (❶). Second, the sender kernel triggers a doorbell register within an FPGA to start a DMA read operation (❷). Third, the *DMA read* module reads the data stream from the “head” slot in the *send buffer* (❸), and then forwards to the 100Gb TCP stack (❹). Fourth, the receiver accepts the data stream from its 100Gb TCP stack (❺), and then adds a header and a trailer to the data stream and forwards it to the “tail” slot in the *receive buffer* in the “GPU kernel” layer (❻). Fifth, the receiving GPU kernel monitors the “head” slot and leverages a data-mover kernel that also occupies a GPU SM to copy the data in the “tail” slot to the destination chunk in the to-*receive array* in the “GPU user” layer (❼).

Flow Control. Reliable communication (goal D1) is achieved through a simple credit-based flow control [34] over each TCP connection, so as to avoid potential congestion at a slow receiving GPU receiving a heavy traffic load. At the beginning, the sender has a full credit of M MB to leverage. If we send data from the to-*send array* to the tail slot in the *send buffer* (❶), the corresponding credits are consumed, and the data in the *send buffer* will be safely delivered to the *receive buffer* on the other side. When the receiver copies the data from the head slot to the to-*receive array* in the “GPU user” layer, and then accumulates the amount M_r of correctly received data, where M_r is initialized to be 0. Once the ratio of M_r to M is over a threshold (Th), the receiver sends back a credit with $Th \times M$ bytes to the sender, indicating $Th \times M$ bytes of data have been correctly received. To do so, the receiver triggers a doorbell register (`consumed_bytes`) specified in the “control” module (❸), and then forms a flow-control packet to the sender (❹). After the sender receives the credits, the sender can proceed to send $Th \times M$ additional bytes.

Table 8: State transition of AllReduce within FpgaNIC. “ x/y ” means that x is input and y is output, where G refers to the communication with a GPU, E refers to the communication with the 100Gb TCP stack. “ $(G + E)$ ” means that we perform the reduction on the data from GPUs (G) and the data from the 100Gb TCP stack (E), and store the reduced result in on-board memory. “ (E, G) ” means that the data is read from on-board memory and forwarded to the next GPU via 100Gb TCP stack (E) and GPUs (G). E_i^j indicates the *subarray*[i] has already been accumulated j times, where $1 \leq j \leq 4$. When j is 4, E^4 and G^4 are the final reduced result sent to the next GPU via 100Gb TCP stack and to local GPU, respectively.

| | t_0 | t_1 | t_2 | t_3 | t_4 | t_5 | t_6 | t_7 |
|---------------|-----------|-------------------------|-------------------------|-------------------------|------------------------|------------------------|------------------------|-----------|
| FPGA 0 | $G_0^1/-$ | $(G_3^1 + E_3^1)/E_0^1$ | $(G_2^1 + E_2^2)/E_3^2$ | $(G_1^1 + E_1^3)/E_2^3$ | $E_0^4/(E_1^4, G_1^4)$ | $E_3^4/(E_0^4, G_0^4)$ | $E_2^4/(E_3^4, G_3^4)$ | $-/G_2^4$ |
| FPGA 1 | $G_1^1/-$ | $(G_0^1 + E_0^1)/E_1^1$ | $(G_3^1 + E_3^2)/E_0^2$ | $(G_2^1 + E_2^3)/E_3^3$ | $E_1^4/(E_2^4, G_2^4)$ | $E_0^4/(E_1^4, G_1^4)$ | $E_3^4/(E_0^4, G_0^4)$ | $-/G_3^4$ |
| FPGA 2 | $G_2^1/-$ | $(G_1^1 + E_1^1)/E_2^1$ | $(G_0^1 + E_0^2)/E_1^2$ | $(G_3^1 + E_3^3)/E_0^3$ | $E_2^4/(E_3^4, G_3^4)$ | $E_1^4/(E_2^4, G_2^4)$ | $E_0^4/(E_1^4, G_1^4)$ | $-/G_0^4$ |
| FPGA 3 | $G_3^1/-$ | $(G_2^1 + E_2^1)/E_3^1$ | $(G_1^1 + E_1^2)/E_2^2$ | $(G_0^1 + E_0^3)/E_1^3$ | $E_3^4/(E_0^4, G_0^4)$ | $E_2^4/(E_3^4, G_3^4)$ | $E_1^4/(E_2^4, G_2^4)$ | $-/G_1^4$ |

Discussion. The design matches the goals we established the beginning, which dictate many of the architectural decisions. To ensure reliable communication (goal **D1**), we implement a credit-based flow control (§A.1.4) on the GPU side. To simplify programming (goal **D2**), the GPU-aware socket-like functions are executed sequentially by leveraging the default CUDA stream, which is transparent to programmers. Nevertheless, our APIs also allow programmers to explicitly specify CUDA streams to maximize execution overlap between kernels. To minimize overhead (goal **D3**), GCN uses at most 220MB of the GPU memory for the communication, and a GPU SM only when a send() or a receive() function is active. Moreover, each handshake function launches a GPU kernel with only one active thread. Finally, to support a wide range of GPU classes (goal **D4**), GCN only exposes 220MB GPU memory, which is allowed in all supported Nvidia GPUs.

A.2 Off-path SmartNIC: AllReduce

To illustrate the the off-path model of FpgaNIC, we implement a use case from HPC and AI applications: a collective communication primitive AllReduce [4, 11, 50] operating on the data residing in a distributed pool of GPUs. In particular, we implement a ring-based AllReduce algorithm [4, 50] as it provides high performance while having a simple communication flow that fits well within an FPGA. The communication pattern is as follows. Assume there are P GPUs and each GPU divides its own array for AllReduce into P subarrays. The p -th GPU receives *subarray*[i] from the $(p - 1)$ -th GPU, performs a reduction operation on the received *subarray*[i] and its local *subarray*[i], and then sends the reduced result to the $(p + 1)$ -th GPU, where $0 \leq i, p < P$.

A.2.1 Overall Architecture of AllReduce

The AllReduce [5, 67] engine implements the entire logic in the ONC component, which is configured in an off-path model, as show in Figure 12. The engine concurrently operates on three components on the FPGA: the PCIe DMA operation (§2.3), the network stack (§2.4), and the on-board memory. The overall execution under FpgaNIC allows to overlap the access to these components to maximize throughput.

PCIe DMA Operation. The PCIe DMA operation is used transfer data between the FPGA and its local GPU by issuing a DMA operation within an FPGA directly to the GPU and without CPU intervention.

Network Stack. The network stack is used to communicate with remote GPUs through their corresponding FPGAs. In our ring implementation, data arrives the previous GPU and it is sent to the next GPU in the ring.

On-board Memory. The FPGA on-board memory is used to store intermediate results. The current reduced result is accumulated in on-board memory before being forwarded to the next GPU. While it is being forwarded, the next result is being calculated. Thus, the memory needs to provide sufficient bandwidth for simultaneously writing partial results and reading the previous result as it is being sent.

Figure 12: Architecture of AllReduce on the off-path model

A.2.2 Execution Flow of AllReduce on FpgaNIC

Table 8 illustrates the detailed execution flow of FpgaNIC-enhanced AllReduce with a concrete example over 4 distributed nodes, labelled FPGA i , where i is from 1 to 4. The execution is divided into eight steps ($t_0 \sim t_7$).

At step t_0 , FPGA i issues a DMA read operation to transfer its local *subarray*[i] in GPU memory to the FPGA’s memory (labelled G_i^1). At step t_1 , FPGA i issues a DMA read operation to read from its local *subarray*[$i-1$] (G_{i-1}^1) in GPU memory, receives E_{i-1}^1 from the previous GPU in the ring (i.e., arriving via the network), and then accumulates these two on-the-fly and finally stores the accumulated result in the FPGA memory (labelled $(G_{i-1}^1 + E_{i-1}^1)$). At the same time, FPGA i

forwards its local *subarray*[*i*] in FPGA memory to the next GPU, labelled E_i^1 . Figure 12(a) illustrates the data flow of FPGA 0. At step t_2 , FPGA *i* performs the reduction operation on its local G_{i-2}^1 in GPU memory and E_{i-2}^2 from the previous GPU, and then stores the accumulated result in FPGA memory (labelled $(G_{i-2}^1 + E_{i-2}^2)$). At the same time, FPGA *i* forwards its local E_{i-1}^2 from the FPGA memory to the next GPU. At step t_3 , FPGA *i* performs the reduction operation on G_{i-3}^1 from its local GPU memory and E_{i-3}^3 from the previous GPU, and then stores the accumulated result in FPGA memory, labelled $(G_{i-3}^1 + E_{i-3}^3)$. At the same time, FPGA *i* sends its local E_{i-2}^3 from FPGA memory to the next GPU in the ring. At step t_4 , FPGA *i* receives E_i^4 from the previous GPU and copies it to FPGA memory. At the same time, FPGA *i* sends $(G_{i-3}^1 + E_{i-3}^3)$ from the FPGA memory to the next GPU E_{i-3}^4 and writes it to its local GPU memory G_{i-3}^4 . At step t_5 , FPGA *i* receives E_{i-3}^4 from the previous GPU and copies into the FPGA memory. At the same time, FPGA *i* sends E_i^4 in the FPGA memory to both the next GPU E_i^4 and writes it to its local GPU memory G_i^4 . Figure 12(b) illustrates the data flow of FPGA 1. At step t_6 , FPGA *i* receives E_{i-2}^4 from the previous GPU and copies it to on-board memory. At the same time, FPGA *i* sends E_{i-3}^4 to the next GPU E_{i-3}^4 and writes it to its GPU memory G_{i-3}^4 . At the final step t_7 , FPGA *i* writes E_{i-2}^4 from the FPGA memory into its GPU memory G_{i-2}^4 which now has the final aggregated result.

Comparison with AllReduce on Innova. To illustrate the advantages of FpgaNIC’s design over existing commercial solutions, consider how the same AllReduce operation would work on Mellanox Innova. In Innova, the PCIe link connecting the FPGA to the rest of the system limits the overall throughput because the AllReduce engine on the FPGA is forced to interact with both the local GPU and the network through its PCIe X8 Gen4 endpoint. In such a design, the FPGA can consume data either from the GPU or from the network but not from both at the same time. We estimate that the overall throughput would be halved. Both Innova and FpgaNIC approaches do not involve any GPU cores during execution, freeing up GPU cores for other computing tasks.

A.3 On-path SmartNIC: HyperLogLog

To illustrate the on-path model of FpgaNIC, we use HyperLogLog (HLL) [18, 33] as an example application. HLL is widely used in data analytic applications to estimate the cardinality of data streams or of large data sets. In our case, HLL will work on the data as it flows from the network transport towards the GPU. The basic scenario is transferring data to be processed to the GPU and using the FPGA to compute the cardinality on the fly without adding any overhead.

The on-path model is similar to the direct model (labelled “direct”), except that the incoming data stream is forwarded to both the GPU and to the on-path module (HLL in this case) via the “op_in” port. We use an open source implementa-

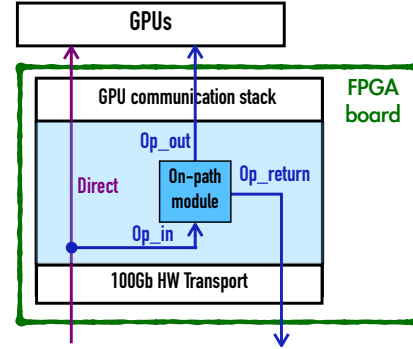

Figure 13: On-path model of FpgaNIC

tion of HLL [33] that is embedded into the ONC component (Figure 13). After the data stream has been consumed, the cardinality of the data set can be forwarded to the local GPU via the “op_out” port. The on-path model also allows the result to be sent back to the network through the “op_return” port. In such a case, FpgaNIC can be used as an independent, network attached accelerator that uses the on-path module to process data on behalf of a remote client.

7 Artifact

7.1 Abstract

This artifact provides the source code of FpgaNIC and scripts to reproduce the main experimental results. The experiments are run on a cluster consisting of eight 4U AMAX servers, connected with a Mellanox 100Gbps Ethernet SN2700 switch. Each server is equipped with two Intel Xeon Silver 4214 CPUs@2.20GHz, 128GB memory, FpgaNIC (i.e., a Xilinx Ultra-Scale+ FPGA), and a Nvidia RTX 8000 GPU, where the FPGA and the GPU have direct PCIe P2P communication. Two servers have an additional two A100 GPUs. FpgaNIC is implemented on Xilinx Alveo cards U50 or U280 with Vivado 2020.1.

7.2 Check-list

1. At least two nodes, each has a GPU that supports NVIDIA GPUDirect and the Xilinx U280 or U50 card.
2. Each FPGA card is connected to a 100Gbps Ethernet switch.
3. FPGA card and GPU are connected to the same PCIe switch.
4. Host OS: Linux 4.15.0-20-generic
5. Nvidia Driver Version: 450.51.05
6. CUDA Version: 11.0

Hugepages Setting. Make sure that each server has enabled Hugepages. If not, run the following commands.

1. \$ sudo apt install libboost-program-options-dev cmake
2. \$ sudo groupadd hugetlbf
3. \$ sudo getent group hugetlbf
4. \$ sudo adduser xxx hugetlbf
xxx is the user name you are using
5. Edit “/etc/sysctl.conf” and specify the number of pages you want to reserve.
6. \$ mkdir /media/huge
7. Add this line “hugetlbf /media/huge hugetlbf mode=1770,gid=1001 0 0” to “/etc/fstab”.
8. \$ reboot

7.3 Thee Steps to Run Experiments

There are three steps to run each experiment. Before running FpgaNIC, please clone the source code:

```
$ git clone https://github.com/RC4ML/FpgaNIC
```

7.3.1 Hardware: FPGA Bitstream

1. \$ mkdir build && cd build
2. \$ cmake ..
3. Make HLS IP core
\$ make installip
4. Create vivado project, add the hardware project option after *make*, as shown in Table 9.
\$ make pcie_benchmark
5. Now the hardware project is produced, generate bitstream using vivado and flush it to every FPGA card.
6. Every time you download the bitstream to the FPGA, you have to reboot the machine, do not forget to reinstall xdma driver and GDR driver (See Subsection 7.3.2).

Table 9: The options of hardware project

| Project | Description |
|-----------------------|--|
| direct | To create direct model project |
| pcie_benchmark | To create PCIe benchmark project |
| tcp_latency | To create TCP latency benchmark project |
| tcp_benchmark | To create TCP throughput benchmark project |
| allreduce | To create off-path model project |
| hyperloglog | To create on-path model project |

7.3.2 Software: Driver Installation

1. \$ cd FpgaNIC/driver
2. \$ make && sudo insmod xdma_driver.ko
3. \$ cd FpgaNIC/gdrcopy
4. \$ sudo ./insmod.sh
5. Note that you need to reinstall xdma driver and gdr driver every time you reboot your machine.

7.3.3 Software: Running Application Code

1. \$ cd FpgaNIC/sw && mkdir build && cd build
2. \$ cmake ../src
3. \$ make
4. \$ sudo ./dma-example -b 0
5. \$ Above command would report GPU read CPU memory latency, for more details, please refer to sw/README.md

Faster Software Packet Processing on FPGA NICs with eBPF Program Warping

Abstract

FPGA NICs can improve packet processing performance, however, programming them is difficult, and existing solutions to enable software packet processing on FPGA either provide limited packet processing speed, or require changes to programs and to their development/deployment life cycle.

We address the issue with *program warping*, a new technique that improves throughput replacing several instructions of a packet processing program with an equivalent runtime programmable hardware implementation. Program warping performs static analysis of a packet processing program, described with Linux's eBPF, to identify subsets of the program that can be implemented by an optimized FPGA pipeline, the *warp engine*. Packets handled by the warp engine are eventually delivered to a regular eBPF program executor, along with their program context (registers, stack), to complete execution of those program parts that cannot be efficiently pipelined.

We prototype program warping on a 100Gbps FPGA NIC, extending hXDP, a state-of-the-art eBPF processor for FPGA, and measure its performance running 6 unmodified real-world eBPF programs, including deployed applications such as Katran and Suricata. Our prototype runs at 250MHz, uses less than 15% of the FPGA resources, and improves hXDP throughput by 1.2-3x in most cases, and up to 18x.

1 Introduction

Datacenter and telecom operators deploy FPGA NICs to handle network port speeds of 100Gbps or more, and to support heterogeneous applications and workloads [12, 21, 30]. In fact, these devices can host multiple accelerators [23], e.g., for radio signal processing, therefore providing a common hardware platform to address different scenarios [11].

Nonetheless, for network packet processing functions, such as firewalls or load balancers, FPGA NICs raise several challenges. First, programming FPGAs is difficult, often requiring dedicated teams of hardware specialists [15]. Second, it involves longer synthesis-implementation cycles that may take

hours to complete, before a new program version can be finally deployed. This is at odds with current practices that foster continuous deployment cycles, and frequent updates to the packet processing programs [1, 7]. Finally, packet processing functions should consume only minimal FPGA hardware resources, to leave space to other accelerators required for signal processing, machine learning, etc.

These requirements, when combined, rule out existing solutions that cannot dynamically change the implemented packet processing programs, such as those based on the high-level synthesis of programs described with domain-specific languages [3, 38, 40] like P4 [8]. Alternative approaches, such as hXDP [10], explicitly address these challenges, but at the cost of a lower packet forwarding throughput. In fact, hXDP implements on the FPGA a processor-based executor for network programs described with eBPF, which provides a remarkable but still limited throughput performance, comparable to that of a single multi-GHz CPU's core [10].

Our goal is to improve on this figure, and significantly increase throughput while respecting the listed requirements. We follow the conceptual approach of hXDP, embracing the Linux's eBPF framework and its programming model to describe packet processing functions. However, we introduce a new technique, *program warping*, which leverages common properties of eBPF programs to automatically replace the execution of many program's instructions with a semantically equivalent hardware-supported implementation, thereby reducing the program execution time and increasing throughput. As we will see, in some real-world use cases our system can achieve up to an 18x higher throughput than hXDP.

Program warping builds on the observation that a subset of the eBPF programs' instructions implement common packet processing tasks, such as packet header parsing, which can be efficiently implemented in pipeline-parallel architectures [9, 13]. Therefore, under the constraint of keeping transparency to the programmer, we address two main issues in our design: (i) identifying, from the eBPF program's bytecode, the tasks that can be efficiently parallelized in a pipeline; (ii) designing an FPGA pipeline that runs such tasks, while providing runtime

Figure 1: Program warping includes two components: an optimizing compiler and a hardware engine for FPGAs

reconfigurability and using minimal hardware resources.

We prototype program warping extending hXDP with a new compiler, the *Warp Optimizer*, and a new hardware module, the *Warp Engine* (cf. Figure 1). The Warp Optimizer performs static analyses of the eBPF bytecode, leveraging the eBPF’s machine model to make several simplifying assumptions, e.g., about memory areas’ content, in order to infer the program’s intent. In this step, the Warp Optimizer identifies set of instructions whose execution can be performed by the Warp Engine. The Warp Engine is integrated with the hXDP’s eBPF executor. Packets received by the system are processed by the Warp Engine first, and then passed to the eBPF executor to run the subset of the program that cannot be accelerated. In turn, this allows us to streamline the Warp Engine implementation, which resembles a fused parser plus match-action pipeline, supporting only the minimal set of functionality required to accelerate common packet processing tasks, and leaving to the eBPF executor any more complex functionality.

We evaluate our system with a 100Gbps Xilinx Alveo U50, running 6 real-world use cases: the IP router and the tunneling examples from the Linux XDP’s application examples; a Dynamic NAT; the Facebook load balancer Katran [14]; and the Network Security Appliance Suricata [39]. On this set of applications and compared to hXDP, program warping provides a per-application speed-up of at least 1.2-3x, and up to 18x, while running at 250MHz and keeping the overall FPGA resources occupation below 15%. To put this result in perspective, running Suricata in software (Linux v.5.4.0) on a single Intel Xeon 4410 CPU core achieves a throughput of about 8.7 Million packets per second (Mpps), whereas our program warping prototype achieves up to 83Mpps in a similar setting. This shows that program warping is beneficial in all cases, but clearer advantages appear with programs that have a heavier packet parsing and classification component. In summary, we contribute:

- A method to extract high-level packet processing tasks from eBPF bytecode, and generate functionally equivalent descriptions that combine parsing descriptions, match-action rules and subsets of the original bytecode;
- A hardware extension to hXDP, which implements high-performance and runtime-configurable packet data reading and classification using few FPGA resources;

- The evaluation of the end-to-end system using 6 real-world use cases and extensive micro-benchmarks.

2 Goal, Requirements and Challenges

Our goal is to provide a significant increase (i.e., >2x) to the throughput of eBPF packet processing programs on FPGA NICs, while meeting the following requirements:

1. The system should run unmodified eBPF programs
2. The system should support dynamic program loading
3. The system should use a small fraction of the FPGA resources (<20%)

This is challenging for several reasons. First, previous work like hXDP already explored the optimization space for eBPF programs on FPGA, leveraging instruction-set specialization and instruction-level parallelism to reduce the number of programs’ instructions and run them in parallel, when possible. This suggests that additional instruction-level optimization is unlikely to provide large gains. Second, our solution space is limited since we cannot change the eBPF programming model. For instance, we cannot pursue any solution that would require programmers to annotate their code, e.g., to discover parallelization opportunities. Third, the need to support dynamic program loading rules out approaches that implement programs as hardware pipelines, e.g., like in Emu [38] and P4->NetFPGA [3]. Finally, the requirement to use little FPGA resources makes effectively impossible to use any solution that requires complex logic implementation in hardware. For reference, even streamlined hardware designs like hXDP already consume about 10% of the FPGA resources.

Non-goal Since we use only a fraction of the FPGA for network packet processing, we do not have the goal of matching the throughput of designs entirely dedicated to the task.

3 Concept and Background

In this Section we provide background about eBPF/XDP, and then present the program warping concept and system design.

3.1 Background: eBPF and XDP

eBPF is a Linux technology used to implement load balancing [14], security [7], monitoring [2], deep packet inspection [5], policy enforcement [1], and more.

The eBPF framework runs small programs within the Linux kernel using a virtual machine (VM) with its own Instruction Set Architecture (ISA). The VM implements a register architecture, with a program counter (PC), 10 general registers ($R0 - R9$), and a read-only stack pointer ($R10$) that contains the address of a 512B memory area used as program’s stack. These capture the current program’s state, which resets for every new run. eBPF provides *maps* data structures to save state across program runs. These are memory areas defined at compile time and organized as lookup tables.

eBPF programs written in a high-level language, such as C, are compiled to the eBPF bytecode. The eBPF bytecode can be loaded in the kernel using different *hooks*. We focus on the XDP hook [19], and call *XDP programs* an eBPF program attached to the XDP hook. The hook is provided at the NIC driver level. When a packet is received, the XDP environment: (i) creates an `xdp_md` struct to contain the packet buffer pointers and metadata, such as the packet’s input port id; (ii) sets *R0* to point to the address of the memory area hosting the struct; (iii) and then starts the VM to run the XDP program. At the end of its execution, the program can return a forwarding decision for the packet by writing the forwarding action code in *R0*.

When loaded in the Linux kernel, the bytecode is statically verified to ensure safety, e.g., guaranteed program termination. To enable verification, eBPF programs can only use a subset of the C expressive power. For instance, unbounded cycles and dynamic memory allocations are not allowed. To finally run on the target hardware, a second (just-in-time) compilation step translates the eBPF bytecode to the target machine code. **Program example** Listing 1 shows an XDP program written in C. The program checks if the source MAC address of IPv4 packets is in a hashtable. If so, it passes the packet to the Linux’s network stack. Otherwise, the packet gets dropped. Furthermore, the program drops any IPv6 packet, and passes to the network stack any packet that is neither IPv4 or IPv6.

Listing 1: A simple eBPF/XDP program example in C

```

1 int l2_acl(struct xdp_md *ctx) {
2     void *data_end = (void *) (long) ctx->data_end;
3     void *data = (void *) (long) ctx->data;
4     void *lookup_res = NULL;
5     __u32 proto, nh_off;
6     struct ethhdr *eth = data;
7     __u8 key[6] = {0};
8     nh_off = sizeof(struct ethhdr);
9     if (data + nh_off > data_end) {
10        return XDP_DROP;
11    }
12    proto = eth->h_proto;
13    if (proto == BE_ETH_P_IP) {
14        __builtin_memcpy(key, eth->h_source, 6);
15        entry = bpf_map_lookup_elem(&map, &key);
16        if (entry) {
17            return XDP_PASS;
18        } else {
19            return XDP_DROP;
20        }
21    } else if (proto == BE_ETH_P_IPV6) {
22        return XDP_DROP;
23    } else {
24        return XDP_PASS;
25    }
26 }

```

3.2 Program Warping

eBPF executors on FPGA have limited throughput when they need to process many eBPF instructions: FPGA designs usually have a low clock frequency (e.g., <400 MHz), making running an instruction expensive. While parallel instructions execution is possible, the level of parallelization is at most 2-3 instructions per clock cycle [10]. Reducing the number of instructions can increase throughput, but *can we achieve functional equivalence with less instructions?*

To answer the question, we studied several XDP programs. We show two examples in Figure 2, where we report the control flow for the program from Listing 1 (a), and for (a subset of) Katran [14] (b), an XDP L4 load balancer deployed in production by Facebook. In all the studied cases, the first part of the program has instructions that only perform reading from the packet data and comparisons with constants. This is the case since network packet processing programs usually perform packet header parsing and classification as a first step. After that, the programs diverge significantly, with operations that are specific to the application logic.

For a hardware implementation, read only access to a single (small) memory means no data hazards to handle (i.e., no read/write conflicts), and that hardware wires routing may be simple, since a single memory contains all the needed data. In fact, the operations of the first program’s part may be described by a few match-action rules, as shown in Table 1

Figure 2: Flow diagrams for the program from Listing 1 (a) and for (part of) Katran (b). The solid lines show the part of the program that only needs reading packet data and comparison operations.

for Listing 1. Rules #1 and #3 only read some bits from the packet and check their value. Rule #2 is more complex, since it requires the execution of the program’s part that includes the lookup and its downstream operations. More generally, this second part of the program requires to read/write memory areas beyond that containing the packet data.

From this observation emerges the core idea of program warping: run the first program’s part on an extremely simple executor, and then use a downstream eBPF processor to run only the remaining, more complex instructions. This enables skipping several instructions, and increase throughput.

3.3 System Design

Without loss of generality, we design program warping as an extension to hXDP (Figure 1), the current state-of-the-art to

| # | eth_proto | action |
|---|-----------|---------------------|
| 1 | IPv6 | DROP |
| 2 | IPv4 | Continue Processing |
| 3 | * | PASS |

Table 1: Match-action rules to implement part of the program from Listing 1. Rule #2 needs additional processing and accessing data beyond the packet’s content.

run XDP programs on FPGA NICs [10]. hXDP provides the XDP environment for the FPGA NIC, and a compiler that takes eBPF bytecode and outputs the machine code for the on-NIC XDP environment. We inherit the eBPF programming and deployment models from hXDP: from the perspective of an eBPF/XDP programmer, program warping does not introduce any change.

Compile time When loading an XDP program’s bytecode to the NIC, program warping extends the hXDP compiler by triggering a new compiler first: the *Warp Optimizer*. The Warp Optimizer performs static analysis on the bytecode to identify the instructions that can *warped*, i.e., they can be run by the Warp Engine. The output of this process is a configuration for the Warp Engine in the form of match-action rules.

Runtime At runtime, the Warp Engine receives packets first, and applies the match-action rules. If a forwarding decision can be already taken at this stage, the Warp Engine sets the value of the XDP Environment’s *R0*, and transfers the packet to the XDP Environment that carries out the forwarding action. If instead the program cannot run entirely in the Warp Engine, then a context restoration is triggered. Context restoration allows the eBPF executor to skip the warped instructions, while ensuring a correct internal state to start processing the remaining instructions. This involves copying data from the packet to the XDP Environment’s *R0 – R9* and stack memory, and setting the program counter to point to the next program’s instruction. The Warp Engine performs such operations in parallel while also transferring the packet to the XDP environment, where finally the processing continues to terminate the program’s execution. That is, the Warp Engine and the XDP Environment work in pipeline: while the XDP Environment processes a packet, the Warp Engine is processing the next packets. This ensures that the introduction of the Warp Engine *never* reduces the system throughput, and that in the worst case it only introduces an often negligible increase (10s of nanoseconds) of the packet processing latency.

4 Warp Optimizer

The Warp Optimizer is a custom compiler that takes as input the eBPF bytecode and produces as output: (i) the set of bits that should be extracted from the packet data; (ii) a set of match-action rules that will replace the *warped* (i.e., removed) program’s instruction; (iii) the description of the context associated to *context restore* actions. The rules’ match conditions are described by a set of couples (*offset*, *length*), which

specify the bits of the packet that should be read. The actions can be of one of the following two types:

- An XDP **forwarding decision** that neither modifies the packet nor the internal state of the system (e.g., the content of the maps), i.e., DROP, PASS, TX or REDIRECT;
- A **context restore** to continue execution in the XDP Environment, configured using the provided program counter and context (i.e., registers and stack content).

Here, there are two important design decisions that allow us to minimize hardware complexity. First, the definition of the match conditions may be thought as roughly corresponding to the definition of packet header’s fields, however the Warp Optimizer (and the Warp Engine) have no knowledge of what a header field is. We purposely avoided the implementation of a complete packet header parser logic [18], opting instead for a simpler set of reads of a sequence of bit vectors from the packet data. This allows us to avoid the implementation of state machines and enables a fully pipelined execution of the bit vector extraction. Second, the Warp Optimizer only provides a forwarding decision action when there is no modification to the packet and no *side effects* due to the packet processing, e.g., map accesses. Modification to the packet would require additional hardware machinery, e.g., to compute values and write them in the specific packet’s positions. Instead, accessing any internal state of the system would increase hardware complexity significantly, requiring a tighter integration with the XDP environment, and introducing potential data hazards due to e.g., read-after-write for packets processed back-to-back in the Warp Engine pipeline [37].

4.1 Program analysis

To extract the Warp Engine configuration, the Warp Optimizer performs static analysis of the input program. Here, recall that XDP programs can implement arbitrary computations, which generally complicates any static analysis task [29]. Nonetheless, eBPF is designed to simplify static verification of programs loaded in the Kernel, which helps also our analysis. In particular, we benefit from the definition of three logically distinct memory areas: (i) the packet buffer; (ii) the stack; (iii) and maps. Each of these areas can be easily identified. The packet buffer is retrieved from the `struct xdp_md`, whose address is in eBPF VM’s register *R1* when a program starts. The stack base address is stored in the read-only register *R10*. Finally, maps are always accessed using a specific eBPF helper function. With this information the Warp Optimizer can trace accesses to the different memory areas, and infer the evolution of the program state.

In greater detail, the Warp Optimizer first builds the program’s *Control Flow Graph* (CFG), e.g., see left part of Figure 3. The CFG is a directed graph, in which each *node* represents a code *block*, i.e., a set of instructions that are all executed if the program’s control flow triggers the execution of the block’s first instruction. The directed edges show how

Figure 3: The operations of the Warp Optimizer for the program from Listing 1: (i) Control Flow Graph analysis; (ii) Match-action rules extraction; (iii) Context identification. All the operations are performed at compile time.

the different blocks might be executed one after the other, depending on the results of (conditional) jumps. Second, the Warp Optimizer converts the eBPF instructions, which use physical registers, into a Static Single Assignment (SSA) form. In this form, physical registers are substituted with variables that identify the instruction that have defined them. This helps the tracking of the values accessed by each instruction, and therefore it allows the Warp Optimizer to identify the accessed packet data, and the values stored into stack and registers.

After these two processing steps, the Warp Optimizer divides the CFG’s blocks in three categories: start node; middle nodes; and terminal nodes. Terminal nodes are the blocks containing as last instruction `exit`, `call` or instructions that write to the packet data. Middle nodes are all the nodes that are not the start or terminal nodes, and they are further categorized in matching and non-matching nodes. This depends on whether the block ends with a conditional jump instruction (matching) or with any other instruction (non-matching).

4.2 Match-action rules generation

Match-action rules generated by the Warp Optimizer are triples $\langle matches, action, priority \rangle$, where *matches* is a list of (offset, length) pairs, *action* is either a forwarding decision or context restore, and *priority* is an integer value where the lower number encodes the higher priority. To generate these triples, the Warp Optimizer runs Algorithm 1. The algorithm defines a zero initialized current priority counter, a list of bitvectors extracted from the packet (*fields*), their corresponding matching values (*matches*), and the current stack and registers. Then, it performs Depth-First Search

(DFS) on the CFG, descending from the start node and stopping when it reaches a terminal node. The paths explored with this way capture the part of the program that can be *warped*.

When performing DFS, the algorithm evaluates all the instructions in the node, updating the current stack and registers state (i.e., the *registers* and *stack* arrays). For each middle node, if it is a matching node, the algorithm creates a copy of the *fields* and *matches*, and adds to them the bitvector checked by the current’s block matching condition. That is, the condition of the conditional jump, and the variable’s value used in the condition, respectively. This corresponds to checking `if packet_data[s:e] == X`, where `[s:e]` identifies a vector of $e - s$ bits in the packet starting at offset `s`, and `X` is an $e - s$ long bitvector. The current *registers* and *stack* are also copied, since the algorithm has to explore the two branches coming after the conditional jump, for which the program’s state will evolve differently. When doing so, the algorithm explores first the branch corresponding to the *jump taken* case. When completing the exploration of that branch, the algorithm comes back to the latest encountered branching point, to explore the other branch, i.e., the one corresponding to the *jump not-taken* case (see right-top part of Figure 3).

A branch exploration terminates when there is a terminal node. After evaluating the instructions in the terminal node, the algorithm creates a match-action rule using the current list of *matches* and the current *priority* value. To define the action associated to the rule, the algorithm looks at the nodes’s last instruction. If it is an `exit` instruction the action is a forwarding decision, defined by the currently evaluated value of the `r0` register. Other-

wise, the action is a restore context action, which includes $\langle pc, restored_stack, restored_registers \rangle$, where pc is the program counter of the instruction immediately following the node's last instruction, $restored_stack$ and $restored_registers$ are the evaluated current stack and registers, i.e., the *context* to be restored (right-bottom part of Figure 3). After the rule creation, the priority counter is incremented. Since the CFG is explored by selecting first the branch-taken path, this ensures that the rules having the longer match list have higher priority, which is then useful to simplify the rule matching logic implementation at runtime.

5 Warp Engine

The Warp Engine is a pipelined implementation of a *fused* packet parsing and match-action unit, in principle similar to those implemented in switching ASICs, such as RMT [9], but with important conceptual differences and simplifications that are enabled by the co-design with the Warp Optimizer. For instance, in the Warp Engine there is no distinction between the input parser and the match-action unit.

Figure 4 shows an overview of the Warp Engine architecture. We can identify three conceptual sub-systems. First, there is a *key extraction unit*, which comprises twelve stages and is in charge of building a 16B long vector extracting bits from the packet data. Second, a *match-action unit* uses the key to perform a lookup for a matching entry, which is associated

with three areas in three distinct memories. These memory areas store the type of action associated with the packet, and the program context (register, stack) that should be restored in case of a context restore action. Finally, the last sub-system is the *context restoration unit*, which extracts the packet data required to build the context for a packet that needs to continue processing at the end of the Warp Engine. In our design, we use hXDP to implement the XDP environment on the FPGA, slightly modifying it to enable the Warp Engine to hook into the registers and stack memories.

An important aspect of the Warp Engine design is that the three sub-systems are part of a single pipeline that by design never stalls. In fact, the only case in which the pipeline stages do not advance processing is when hXDP is busy processing a previous packet, and therefore the hXDP's Active Packet Selector cannot host a new packet in its buffer memory. This design has also a second effect, since hXDP is still in charge of the forwarding of each and any packet, the Warp Engine has no impact on the packets ordering.

5.1 Key Extractor

The Key Extractor is connected to the packet input queue through a *splitter*, which duplicates the first 128B of the packet to forward them to the Key Extractor's pipeline. The pipeline includes 12 stages, and each of them implements a configurable extractor module. The extractor reads up to 2Bs from the duplicated packet chunk, performs a simple bitwise operation on them, e.g., and, with a 2B long constant value, and finally writes the result of such operation to a lookup key buffer. Which bytes to read, what operation to perform, and the value of the constant are all runtime-configurable parameters that are provided by the Warp Optimizer. Each extractor performs its operations in a single clock cycle, and passes to the next extractor: (i) its modified lookup key buffer; (ii) the offset at which to write in such buffer; (iii) the packet chunk.

5.2 Match-action Unit

The match-action includes a ternary-addressable content memory (TCAM), and three memory areas: (i) the *Action Memory*, to store the actions associated to the TCAM entries, including action type, $R0$ value and program counter; (ii) *Registers Configuration Memory*, which stores the Context Restoration Unit's configuration to extract the register values; (iii) *Stack Configuration Memory*, which provides a similar configuration but related to the stack. These three areas are organized in *lines* of different sizes, and for each memory the number of lines is equal to the maximum number of TCAM entries. The lookup key provided by the key extractor is used to find the matching entry in the TCAM, which is associated to a single *line number* that is then used to access in parallel the three memory areas. If the line extracted from the action's memory includes an action of type forwarding decision, then the pipeline propagates only such line to the next stage, to

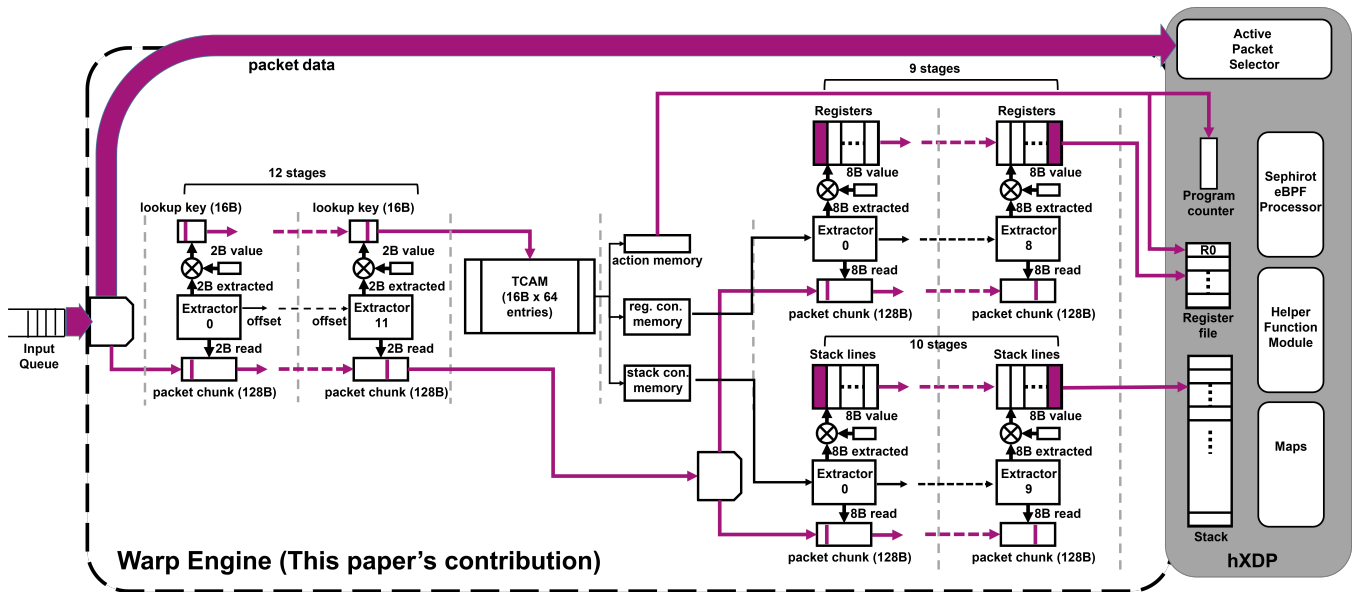

Figure 4: Warp Engine's architecture. The pipeline stalls only when hXDP is not ready to receive a next packet.

eventually configure the XDP Environment. Otherwise, each of the three lines extracted from the three memories is provided to the downstream pipeline. The memory lines contain the full configuration for the Context Restoration Unit, in order to build the stack and registers values. Both the TCAM entries and the memory lines are configured at runtime with the output of the Warp Optimizer.

5.3 Context Restoration Unit

The Context Restoration Unit comprises two parallel pipelines, which are composed of modules closely resembling the Extractor modules of the Key Extractor. However, instead of reading just up to 2B from the packet chunk, the extractors of the Context Restoration Unit can read up to 8B each. This is in line with the eBPF VM's registers size (64bit). Furthermore, they replace the lookup key buffer with larger buffers to host either the partially reconstructed stack or the reconstructed registers' state. Finally, instead of an offset, each extractor provides to its downstream extractor the line read from either the Registers Configuration Memory or the Stack Configuration Memory, depending on which of the two parallel pipelines the extractor belongs to. Here, we point out that this approach was needed since the Context Restoration Unit has an additional complexity element when compared to the Key Extractor. The Key Extractor configuration is the same for any received packet, whereas the configuration for the Context Restoration Unit strictly depends on the content of the received packet. Since the entire system is organized in a pipeline, each stage of the Context Restoration Unit has to carry along the configuration to restore the context for the specific packet being processed in that stage.

These two parallel pipelines are fed by a second *splitter* that duplicates the packet chunk. The pipeline that restores

the Stack has 10 stages, and it is connected to the Stack Configuration Memory. The line extracted from this memory provides to the Extractors the information needed to populate the stack, including constant values and values extracted from the packet chunk. This information includes: (i) the offset at which the packet chunk should be read; (ii) the operation to be performed on the read byte (and the constant value associated to that); (iii) the target address in the stack. The pipeline that restores the Registers has 10 stages too, including 9 Extractors and a Delay element. This is the case since only 9 registers need restoration ($R1 - R9$) and the Warp Optimizer ensures that $R0$ is only read if its value is changed by the loaded XDP program after restoration.¹ The Delay element is required to synchronize the two context restoration pipelines.

5.4 Integration with hXDP

The Warp Engine pipeline ends in hXDP. Here, the Warp Engine waits for hXDP to be available to receive packets. Once that is the case, it first copies the packet data in the hXDP's Active Packet Selector (APS). The packet data transfer is also pipelined, and it happens in synch with the Warp Engine's pipeline. That is, multiple packets' data are moved through the pipeline at each clock cycle, using a 64B datapath (matching Corundum's datapath). Then, we have two possible behaviors. If the current action memory's line contains a forwarding action, then the Warp Engine sets $R0$, and instructs the APS to proceed with packet forwarding. The APS will then carry out forwarding according to the value provided in $R0$. Instead, if the action is a restore context action, then the Warp Engine sets the hXDP's program counter, registers ($R1 - R9$)

¹Register $R10$ is read-only, and in hXDP it has a constant value. $R0$ is used to store the return value of helper function calls, which are usually the first instruction run by the program after restoration.

| <i>Application</i> | <i>Instructions</i> | | <i>TCAM Entries</i> | <i>Match size [B]</i> | <i>Max Stack size [B]</i> |
|--------------------|---------------------|-------------|---------------------|-----------------------|---------------------------|
| | <i>eBPF</i> | <i>hXDP</i> | | | |
| L2 ACL | 40 | 27 | 3 | 2 | 6 |
| Router | 119 | 95 | 9 | 4 | 8 |
| Tunnel | 283 | 155 | 7 | 4 | 24 |
| DNAT | 228 | 135 | 6 | 6 | 40 |
| Suricata | 138 | 65 | 49 | 12 | 40 |
| Katran | 1398 | 1013 | 20 | 16 | 80 |

Table 2: Tested applications and key metrics

and stack, and starts the hXDP’s Sefirot eBPF Processor. Sefirot will then run the XDP program starting from the instruction pointed by the program counter, and using the provided registers and stack values.

5.5 Implementation

We implemented the Warp Engine design using the latest version of hXDP, which is integrated in Corundum [16], clocked at 250MHz, and targets a Xilinx Alveo U50 FPGA NIC [4]. The Warp Engine is clocked at 250MHz too, and its pipeline is 28 clock cycles long. Since at 250MHz each clock cycle takes 4 nanoseconds, the Warp Engine introduces a fixed 112 nanoseconds of latency to each processed packet. This is a negligible overhead in the vast majority of cases, and it is the only runtime overhead introduced by the Warp Engine.

Our design has several parameters, e.g., the number of Key Extractor stages and the packet chunk size, which may be changed to meet different use case requirements. We summarize them in Appendix, along with the configuration we implemented in this paper, which is driven by the requirements of the 6 use cases we tested during evaluation (cf. Table 2).

6 Evaluation

In this Section we evaluate correctness, optimizations, resources requirements, and performance of our prototype.

6.1 Applications

We use 6 different applications to perform the evaluation, as detailed next. Table 2 summarizes them and reports relevant metrics, including their requirements in terms of Warp Engine’s TCAM entries, lookup key size and max Stack size. **L2 ACL (Running example)**. This is the application we used as running example, and described in Section 3.1.

Dynamic NAT. Network Address Translation (NAT) for flows coming from a LAN and destined to a public network, and reverse translation. The application has two main branches: (i) one for packets originated from the the LAN, and (ii) the other for those coming from the public network.

XDP Router. An implementation of an IPv4/IPv6 router, provided as eBPF application example with the Linux Kernel. It performs parsing of L2 and L3 headers, and then a lookup in two tables to take a packet routing decision.

XDP TX Tunnel. This is another eBPF application example provided by the Linux Kernel. It performs IPinIP encapsulation matching on destination IP address and destination L4 port. A lookup in a hashtable matches on the destination virtual IP address to retrieve the tunnelling information.

Suricata IDS. Suricata [39] is a software Intrusion Detection System (IDS). Among its multiple features, it provides an XDP program that works as a filter, to perform early dropping of undesired flows. The XDP program contains a large number of processing branches to handle all the combinations of stacked 802.1Q and 802.1AD VLAN headers, and performs a lookup in a hashmap to take some of the filtering decisions.

Katran. Katran [14] is an XDP-based Layer 4 load balancer. It encapsulates packets with a specific destination Virtual IP addresses and balances the connections towards the available servers. The first part of the processing includes L3 parsing and handling of ICMP/ICMPv6 protocols. Then, a first map lookup retrieves the virtual IP information. The application uses this information to query a Least Recently Used (LRU) map, in order to fetch the address of a connection table. A query to the connection table finally retrieves the real IP address of the destination server.

6.2 Functional Equivalence

Program warping modifies a program to run it on a system that comprises two different executors. We therefore performed tests to verify that the resulting behavior matches the original program behavior. In particular, for each of the tested applications, we: (i) enumerate all the program’s control paths; (ii) generate input packets that trigger the execution of each of the listed paths; (iii) and finally verify the produced output, for all the generated input packets. We run these steps for the 6 applications described earlier, verifying that program warping keeps functional equivalence. More details are in Appendix.

6.3 Warped instructions

We now evaluate the number of instructions that can be skipped thanks to program warping, since their functionality is implemented by the Warp Engine. This requires evaluating the instructions being actually executed at runtime. We use uBPF [22], a userspace eBPF processor, extending it to implement a Warp Engine emulator in software, to compute the number of actually executed instructions for all the tested applications, and for all the control flow paths of each application. Since the control path at later stages of the program depends also on the stored state, e.g., entries in the maps, our testing strategy is adapted to test the multiple possible state conditions. For instance, in the case of the L2 ACL, after the map lookup there are two different paths: if the lookup returns an entry; or not (cf. Listing 1).

Figure 5 reports the results, showing the total number of eBPF instructions executed per path (background bar), and the number of instructions executed when program warping is

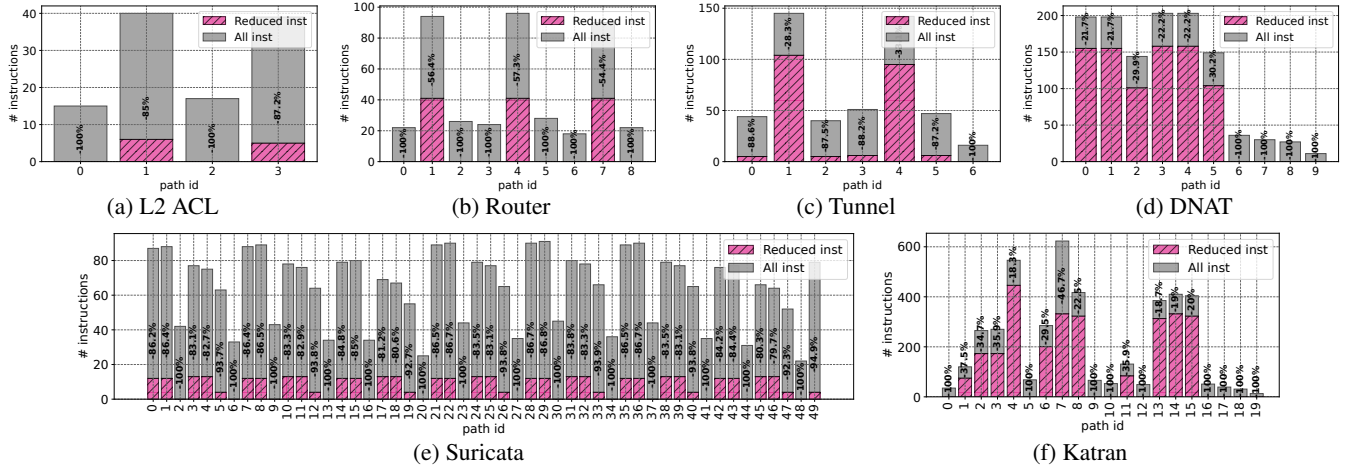

Figure 5: Number of instructions per program’s control flow path (background bar) vs number of instructions executed per path with program warping (foreground bar). Program warping reduces the instructions to be executed by 50-100%.

in place (foreground bar). The results show that in many cases the number of instructions to be executed by the eBPF processor is reduced by over 50%, and that anyway in all cases it is reduced by at least 16.3%. More precisely, an application’s control flow paths belong to one of two general categories, based on where their execution is going to be implemented: (i) *Mostly Warp Engine*; (ii) and *Mixed*.

Mostly Warp Engine In all the applications there are at least a few control paths whose processing is mostly implemented by the Warp Engine. This is due to the practice of including in the programs several checks to take an early forwarding decision. Many of these early decisions are taken to *protect* programs from bogus or malicious traffic, which has an interesting implication: program warping may provide higher performance boosts when it is the most needed. For instance, some Denial-of-Service attacks’ traffic may be entirely handled by the Warp Engine. Consistently, we can observe that all the control flow paths of Suricata fall in this category. In fact, Suricata generates XDP programs to filter network traffic as early as possible. As a result, in some cases the entire program is implemented by the Warp Engine. More generally, in Figure 5e we can see that the instructions reduction depends on the specific path, and it is in the range 82%-100%.

Mixed Some control flow paths split their execution between the Warp Engine and the eBPF processor, either in equal parts or mostly using the latter. This is the case for, e.g., Router, Tunnel, and DNAT. In such cases, the packet parsing and lookup key extraction are delegated to the Warp Engine. The rest of the application logic, e.g., lookup in a single map and packet header mangling, is performed by the eBPF processor. In some programs, this second part is relatively simple. For instance, we see that program warping reduces the instructions of these paths by 54%-57% and 51% for Router (Paths 1, 4, 7). In some applications, this second part is instead more complex. For instance, the Tunnel application’s paths 1 and 4 are reduced by 28% and 33%, respectively. This is the case

| | Logic Res. | | Memory Res. | |
|------------------------|------------|-------|-------------|-------|
| | LUTs | Reg. | BRAM | URAM |
| Corundum (C) + hXDP | 10.7% | 6.91% | 13.65% | 2.34% |
| C + hXDP + Warp Engine | 16.8% | 9.86% | 14.51% | 8.44% |

Table 3: FPGA resources usage

since these paths have a large number of instructions that deal with the packet encapsulation, which happens after a map lookup. Similarly, in the first six DNAT application paths, the reduction ranges between 21%-31% due to the high number of instructions required to recompute the checksum and packet modifications after the program warping. In Katran’s paths this is even more evident due to the many lookups in maps performed in the program’s paths. The reduction, in this case, ranges from 16.8%-34.7%.

6.4 Warp Engine Hardware Requirements

We now evaluate the FPGA resources required by the Warp Engine. We compare the requirements with those of the latest hXDP version [4], which is integrated within the Corundum NIC [16] and targets a Xilinx Alveo U50. The U50 is equipped with a Xilinx Ultrascale+ FPGA, which offers 4 main types of resources that are of interest to us: (i) Lookup-Tables (LUTs); (ii) registers; (iii) block RAM (BRAM); and Ultra RAM (URAM). The LUTs and registers are the main building blocks to implement logic functions, whereas BRAM and URAM are two different memory blocks provided by the FPGA. BRAMs provide multi-port access, whereas URAM have a single read/write port but they are larger than BRAMs. For all the resource types, the Warp Engine is within our original requirement of keeping the packet processing subsystem below the 20% of the available FPGA resources (Table 3).

6.5 End-to-end performance

We finally test the end-to-end system when processing traffic, measuring both packet throughput and forwarding latency.

Testbed We use two machines: a first machine is equipped with a 100Gbps Mellanox ConnectX-5 NIC, and it runs a DPDK-based traffic generator/receiver, capable of sending traffic at 100Gbps with 64B packets, i.e., ~ 150 Mpps; the second machine is equipped with a single port 100Gbps Xilinx Alveo U50, connected back-to-back with the first machine. In all the tests, we measure packet forwarding that is handled entirely within the NIC, and drops. In this last case, we gain visibility by placing a dedicated drop counter within the FPGA design. Latency is always measured at the packet generator’s machine, as difference between the packet reception and packet sent (hw) timestamps. We do not measure the performance of processing that involves transferring packets to the host system, since the Corundum’s network driver can forward few Mpps, and it would therefore become the system’s bottleneck [16]. However, we remark that in terms of Warp Engine+hXDP design, the transmission to a NIC’s port or to the PCIe bus is implemented with the same hardware logic, therefore our system tests are representative of both cases.

Baseline We perform a baseline test to measure throughput and latency when 100% of program’s instruction are implemented by the Warp Engine. Since the Warp Engine pipeline performs the same steps for all the applications and execution paths, the performance is the same in all the cases. That is, we achieve ~ 83 Mpps, when performing DROP, and 50Mpps with a 1 μ s of per packet end-to-end latency when forwarding packets (TX). This is the same performance achieved by hXDP when running a program with a single instruction.² In fact, the Warp Engine relies on hXDP to carry out the forwarding action, and this performance matches the hXDP baseline performance, confirming that the Warp Engine is never a bottleneck in our design. In fact, this result holds true even when forwarding small packets that are larger than the Warp Engine packet datapath, e.g., 65B long packets.³

Applications Each application has multiple execution paths, which are taken depending on the received traffic and application’s state. For paths that are 100% processed by the Warp Engine, the performance is the same of the baseline case, for all applications and paths. This often provides throughput improvements of over 10x for such paths (E.g., see last row of Table 4). For the remaining paths, in the interest of space, we report the performance for only a subset of them, focusing on those that are the most frequent cases, or on cases that are interesting to study the system behavior. In particular, for L2 ACL, DNAT and Katran, we select the paths corresponding to successful lookups in the maps, which are the most frequent cases. For instance, this would be the path taken by established connections in both the DNAT and Katran cases. For Suricata, we see from Figure 5e a periodic pattern, which is due to the repetition of several different packet parsing

combinations (e.g., including or not multiple levels of VLAN parsing). Among these, we select the worst case for program warping, i.e., the path corresponding to the most instructions executed by hXDP. Finally, for Router and Tunnel, we analyze traffic traces to select the most common paths that would be triggered by processing such traffic. For Router, we use a Datacenter trace [6], and the path handling IPv4 is triggered in over 80% of the cases. For Tunnel, we use a MAWI trace [28], and the case IPv4+TCP is triggered in 60% of the cases.

We summarize the results in Table 4. For the selected execution paths, program warping improves throughput by 1.23x-3.08x, and increases latency in the worst case by only 104 *nanoseconds*. We can make two important observations. First, program warping provides remarkable throughput improvements, nonetheless, comparing to results from Figure 5, it seems that the tested paths provide a lower-than-expected speed-up. For instance, for the L2 ACL’s path #1, Figure 5a shows that only 15% of the instructions should be executed, which would suggest a potential throughput increase of over 6x. However, our test measures a 1.7x increase. This is the case since different hXDP instructions have different costs. For example, a `call` instruction may cost several clock cycles, and it also depends on variables such as the lookup key length. Therefore, the absolute number of instructions at compile time is not necessarily a good estimator for the achievable performance at runtime. Furthermore, it is important to notice that the Warp Optimizer works on the eBPF bytecode, which at a later stage is transformed by the hXDP compiler. The hXDP compiler may remove some instructions and parallelize others, therefore modifying the total program length (cf. Table 2). A side-effect of this is that the *warped* instructions may have been finally removed or parallelized by the hXDP compiler, which reduces the relative gain obtained by avoiding their execution. Second, in the case of Katran we observe a reversed result. Katran’s throughput is improved to 2.3x, despite Figure 5f shows only an 18.7% reduction for the path #11’s instructions. This is due to the relatively large number of (conditional) jumps in the first part of the Katran’s execution path. These jumps introduce bubbles in the hXDP’s processor pipeline, lowering throughput and increasing latency. In fact, Table 4 shows that in the case of Katran the Warp Engine significantly improves also forwarding latency, lowering it from 1.9 μ s to 1.5 μ s.

To put this in perspective, for the Router, Tunnel and DNAT cases the throughput of hXDP+Warp Engine (clocked at 250MHz) matches that of an Arm Cortex A72’s core clocked at 2.75GHz (A processor in use in high-end SmartNICs [32]). For Katran, the throughput is similar to that provided by two A72’s cores. In the case of L2_ACL and Suricata, our prototype matches the performance of four A72’s cores. More details about this are provided in Appendix.

²hXDP takes 3(5) clock cycles to handle drop(forward), with 64B packets.

³The interested reader can find more insights about the implications of datapath size on the packet forwarding throughput in [44].

| Application [Path ID] | Latency [ns] | | Tput [Mpps] | | Tput w/WE vs w/o WE |
|---|--------------|--------|-------------|--------|------------------------|
| | w/ WE | w/o WE | w/ WE | w/o WE | |

Table 4: Warp Engine (WE) End-to-End Performance

7 Discussion

Actual Performance Program warping throughput improvement depends on: (i) the XDP program; and (ii) on which program’s control path is executed. In our evaluations, we only measured a subset of the program’s paths. In operational settings, other control paths are likely to be part of the workload. In some cases, this may dramatically increase the performance gain. For instance, in Suricata, the last row of Table 4 shows the performance for one of the cases in which the Warp Engine can entirely offload hXDP. In this case, the system provides an 18.2x throughput increase. It is worth noticing that these paths are not necessarily uncommon or rarely executed. On the contrary, often they may represent the most frequently taken paths. For instance, CloudFlare defines XDP programs to perform early packet dropping for DDoS protection [7]. In such applications, these highly boosted paths are expected to be handling the majority of traffic.

Programming for Performance This last observation highlights that the performance of the loaded program is not guaranteed, and instead it depends on the received input. While this is sometimes considered an issue in switching devices [9], this is an expected behavior for software programmers who are already used to handle such variability in performance. A related interesting observation is that programmers can describe processing *rules* using `if` statements and *hardcoded* variables and constants, to improve throughput. This is the same set of techniques used to optimize XDP programs running within the Linux kernel on x86 processors. That is, program warping aligns to both the XDP programming model and best practices to improve program performance, matching XDP programmers’ expectations.

Configurability Our current program warping design is quite general, since the 6 presented applications include a good variety of cases. Nonetheless, there may be some other applications for which the Warp Engine resources cannot entirely describe the instructions that can be warped. While falling back to the eBPF executor is always a viable option, we also point out that it is possible to change several parameters of our design to accommodate different applications (e.g., lookup key’s size, TCAM entries number, etc.).

Limitations The performance acceleration provided by program warping strictly depends on the share of instructions that a program dedicates to packet parsing and classification. If the majority of the runtime is spent in other parts of a pro-

gram execution, program warping will only provide small benefits. Conversely, there could be cases in which the warp engine cannot offload all the program instructions that can be in principle *warped*. For example, this is the case if the Key Extractor’s pipeline is too short to extract all the data needed for parsing. In such cases, the Key Extractor and Context Restoration Unit’s pipelines length provides a hard limit to the maximum number of instructions that can be warped.

Scaling throughput The Warp Engine is not the system’s bottleneck. Therefore, for throughput oriented solutions where FPGA resources are available, it is possible to envision a design in which the Warp Engine serves packets to multiple hXDP modules that work in parallel. Similar high-throughput solutions is something we plan to explore as future work.

Portability While in this paper we use program warping to improve hXDP, the approach has more general applicability. In particular, the Warp Optimizer can be decoupled from the underlying hardware platform. For example, the extracted parsing logic can be used to automatically generate packet parsing programs specified with P4, or to map it to DPDK’s `rte_flow` API calls, to configure the underlying NIC packet parsing capabilities. Here, a challenge is to describe efficient mechanisms to move the partial *execution context* from e.g., the device subsystem performing header parsing and the subsystem that executes the remaining part of the program. Thus, the benefits of the approach vary depending on the specific target, which opens an interesting opportunity for future research. The Warp Engine design is also portable to different platforms, beyond FPGAs. In fact, it is a parametrized but “fixed” pipeline, thereby requiring relatively little changes to be ported to an ASIC implementation.

8 Related Work

A large number of new NIC designs appeared in the last few years [17, 20, 27, 32, 34, 41]. These solutions mostly combine in a mix-and-match manner different compute and network modules, e.g., regular NIC’s switching ASICs with general purpose compute clusters based on RISC cores [32], or FPGA-enhanced switching combined with general purpose clusters [20, 41]. In many of the solutions, a novelty factor is enabling P4-based programming of the switching ASIC. This effectively corresponds to replacing the fixed-function switching module with a programmable switching module [34]. However, in all these designs the data plane needs to be explicitly programmed with the provided tools, e.g., based on P4. Some of these designs offer (partial) eBPF support. However, they implement eBPF on top of the general purpose clusters, replicating the architecture commonly used in server machines, but on a smaller scale (including the need to transfer data from the switching ASIC to the general purpose compute clusters using an internal bus). In research, previous work addresses the challenges of moving data among these modules [25], and explores ways to

leverage these new NIC designs to improve application performance [12, 15, 24, 26, 35, 36, 43]. Program warping focuses specifically on the design of the packet switching module, targeting FPGA NICs, and presenting a solution that integrates with Linux applications that leverage eBPF/XDP. We extend hXDP [10], which to the best of our knowledge is the only solution providing full support for XDP on FPGA NIC directly within the switching module. Compared to hXDP, we provide better performance introducing a new compilation step co-designed with a hardware module, the Warp Engine, which is pipelined to the hXDP processor.

Recent work addressed eBPF programs optimization at compile time, targeting x86 processors [29, 42]. These works share with us the challenge of performing static analysis of the programs, and leverage some of the insights we discussed about the eBPF execution model. However, they focus on implementing compiler techniques targeting a fixed processor design, whereas we co-design the compiler and the hardware executor. Another related work is Gallium [43], which targets the offloading of a program's part to programmable switching ASICs. Also in this case, it assumes a fixed set of executors, including programmable switching chips and processors. Program warping, instead, introduces both a compiler and hardware design that integrates with the XDP processor, in order to push the intermediate computations context directly within the processor environment.

9 Conclusion

We introduced program warping, a method that leverages compiler-hardware co-design to accelerate the execution of eBPF programs running on FPGA NICs. Program warping enhances existing systems that run eBPF on FPGA NICs with a new compilation step and adding a hardware module, the Warp Engine. The compilation step identifies parts of eBPF programs that can be more efficiently implemented by the Warp Engine, which offloads them from eBPF processors, improving throughput (120%-300%, and up to 18x) at the cost of a small amount of additional FPGA resources. The crucial insight is that only packet data reads and comparisons are needed to implement the identified program parts. Therefore, the Warp Engine supports this minimal set of operations, thereby achieving speed and efficiency, while eventually concluding packet processing on a regular eBPF processor that could handle any more complex program's functions.

Appendices

A Warp Engine Parameters

In Table 5 we report a subset of the parameters that can be configured in the Warp Engine. This is helpful to accommodate different workloads, or to tune the FPGA resources requirements to the workload of interest in the specific deployment. For instance, there may be cases in which a packet chunk of 64B is sufficient to extract the entire packet context. Likewise, there may be needs to extend the lookup key beyond 16B, etc.

| Parameter | Val. | Description |
|---------------------------|------|--|
| Packet chunk size | 128B | Number of packet's bytes that can be read to build the lookup key (also affects the TCAM entries width). |
| Lookup key size | 16B | Size of the lookup key used in the match-action unit |
| Key Extractor Stages | 12 | Corresponds to the maximum number of different places that can be read in the packet chunk |
| Key Extractor read size | 2B | Maximum number of contiguous bytes that can be read by each Key Extractor's stage (also affects the maximum size of the constant value used for the bitwise operation) |
| TCAM entries | 64 | Maximum number of match-action entries that can be configured by the Warp Optimizer for a given program |
| Stack Extractor Stages | 10 | Corresponds to the maximum number of different places that can be read in the packet chunk |
| Stack buffer | 136B | Maximum number of stack bytes that can be restored |
| Stack Extractor read size | 8B | Maximum number of contiguous bytes that can be read by each Stack Extractor's stage (also affects the maximum size of the constant value used for the bitwise operation) |
| Reg. Extractor Stages | 9 | Corresponds to the maximum number of different places that can be read in the packet chunk |
| Reg. Extractor read size | 8B | Maximum number of contiguous bytes that can be read by each Stack Extractor's stage (also affects the maximum size of the constant value used for the bitwise operation) |

Table 5: Warp Engine's main design parameters, and the values used for the design tested in this paper.

B Applications

Here we report a slightly more detailed description of the application used during our system evaluation (and reported in the paper).

L2 ACL (Running example). This is the application we used as running example, and described in Section 3.1. It includes three branches: the main processing branch handles IPv4 packets and checks whether the source MAC address is present in the access list; the other two branches handle IPv6

packets, which are always dropped), and any packet that is not IP, which is passed to the networking stack.

Dynamic NAT. Network Address Translation (NAT) for flows coming from a LAN and destined to a public network, and reverse translation. The application has two main branches: (i) one for packets originated from the the LAN, and (ii) the other for those coming from the public network. When a flow's first packet from the LAN is processed, the application selects a new *NATed* port, and saves it in the NAT binding table using the 5-tuple as flow identifier. Then it performs address translation and forwards the packet. For any following flow's packet, the application retrieves the NATed port, and performs address translation accordingly. In a similar way, packets from the public network are subject to a reverse NAT if there is a corresponding entry in the NAT binding table, or they are dropped otherwise.

XDP Router. An implementation of an IPv4/IPv6 router, provided as eBPF application example with the Linux Kernel. It performs parsing of L2 and L3 headers, and then a lookup in two tables to take a packet routing decision. The first table is an exact match table that looks up the entire IP destination address. If the lookup in the first table fails, the application performs a second lookup in a Longest Prefix Match (LPM) table.

XDP TX Tunnel. This is another eBPF application example provided by the Linux Kernel. It performs IPinIP encapsulation matching on destination IP address and destination L4 port. The application works with both IPv4 and IPv6, with the two main processing branches handling these two cases to assign the proper IPv4 or IPv6 encapsulation. A lookup in a hashtable matches on the destination virtual IP address to retrieve the tunnelling information.

Suricata IDS. Suricata [39] is a software Intrusion Detection System (IDS). Among its multiple features, it provides an XDP program that works as a filter, to perform early dropping of undesired flows. The XDP program contains a large number of processing branches to handle all the combinations of stacked 802.1Q and 802.1AD VLAN headers. After VLAN parsing, it processes differently IPv4 and IPv6 packets, and performs a lookup in a hashmap providing the 5-tuple plus the (optional) VLAN identifiers to take some of the filtering decisions.

Katran. Katran [14] is an XDP-based Layer 4 load balancer. It encapsulates packets with a specific destination Virtual IP addresses and balances the connections towards the available servers. The first part of the processing includes L3 parsing and handling of ICMP/ICMPv6 protocols, for early response to echo request messages. Then, a first map lookup retrieves the virtual IP information. The application uses this information to query a Least Recently Used (LRU) map, in order to fetch the address of a connection table. A query to the connection table finally retrieves the real IP address of the destination server. If a destination is not found, and the packet has the SYN flag set, then Katran installs a new forwarding rule in

the connection table to ensure forwarding consistency for the following packets of that flow.

C Software Emulator

For some of the Warp Optimizer evaluations, we used a Warp Engine emulator based on `uBPF` [22]. Here we give additional details about such implementation.

Figure 6: MAT+uBPF Architecture

`uBPF` is an open source project that implements an eBPF processor in userspace. Unfortunately, out of the box, `uBPF` misses relevant functional blocks, such as maps. We therefore used OKO [33], an open source project providing an eBPF engine for OpenVSwitch, to enhance `uBPF` with the OKO’s maps and helper functions implementations. Starting from this basis, we further extended this implementation to include any additional feature required by the Warp Engine (cf Figure 6).

Our implementation takes several input files to configure its internal modules. First, we implemented a program that reads the ELF files provided by the standard LLVM eBPF compiler, and which creates as output:

1. a text file containing the *eBPF instructions*, formatted as a sequence of bytes representing the 64bit instructions of the program;
2. a JSON file describing the XDP program’s map definitions. Such information includes the key size, value size, number of entries and type of map (array, hashmap, etc.).

These two files are provided to our software emulator to configure the eBPF executor, and create the maps required by the program.

The emulator’s Warp Engine module implements a Match Action Table (MAT) with ternary match values. The MAT is configured using the output generated by the Warp Optimizer. **uBPF execution** The emulator takes packet in input by reading a PCAP file. It can then be run in two different modes of operation: with the software Warp Engine disabled; and with the software Warp Engine enabled.

In the first case, the MAT is bypassed and the packet is directly fed to the eBPF executor, which applies the eBPF instructions on the packet data. With the MAT enabled, instead, the packet data is used to extract the fields needed to perform

a lookup in the MAT. The matched entry contains the action that must be performed on the packet, that is:

- a standard XDP return code (DROP, ABORT, PASS and TX), so in this case the packet bypasses the eBPF execution stage;
- a context restoration action, which contains the information to construct and restore the context.

In case of context restoration, we copy the registers and stack values as described in the action (which is configured from the Warp Engine’s output). Then, in any case, the program counter is updated with the one required by the matched action, and the regular eBPF execution starts. Finally, the emulator outputs a number of global and per-packet statistics:

- one PCAP trace for each XDP return code, for packets that have been subject to the DROP, PASS, ABORT and TX XDP actions;
- the list of instructions executed for each packet;
- the number of instructions actually executed;
- the number of times a rule in the Match Action Table has been matched.

These statistics have been collected to construct the results shown in Section 6.

D Functional Equivalence

We provide more details about the strategy we used to check functional equivalence of programs running with and without program working. In particular, we validate the equivalence of running an eBPF program in our accelerated system and running the same program in the standard Linux kernel XDP implementation. First, we analyze the *behavioral equivalence*, i.e. that the packets out of the Linux kernel implementation exactly match the packets in output from our software implementation. This is a black-box test and has two outcomes: (i) it validates the equivalence between the standard implementation and our accelerated version, and (ii) it validates the correctness of our software prototype. For what concerns the test cases, for each application we use synthetic packet traces in which each packet exactly matches one entry in the Match Action Table. We run an eBPF program with and without the MAT enabled and compare the output packet traces. We obtain the behavioral equivalence by verifying that the two outputs match exactly, in terms of packet data and associated XDP action.

Nonetheless, a careful choice of the test cases should take into account all the possible inputs such that the totality of the eBPF instructions of a program are covered. For example, in the NAT application, the first packet of a new connection matches the same entry of subsequent packets, but for the first packet the processing is different, and the instructions covered are different as well. In other words, we should take into account the state updates in the execution of a program. To validate the correctness of our test cases to cover the entire set of program’s instructions, for each application we crafted

the packets to cover all the branches in the Control Flow Graph, along with the correct configuration of the eBPF map entries. For every use case considered, we achieved the full program instructions coverage. We verified this by checking that the enumerated instructions represent the totality of the original program.

In the case of Katran, we used a simplified version by removing some parts of the code for which the instructions could not be executed. For example, some portions of the Katran code rely on timeouts triggering a certain condition. Since our uBPF prototype does not implement timers, we removed those program parts. In any case, all the instructions that are not covered by our tests always happen after the *warped* part of the program, therefore we could still verify that program warping does not modify in any way a program's behavior.

E Comparison with commercial SmartNICs

In Section 6 we compare our prototype only with hXDP. This is the case since we are not aware of any other NIC platform that supports running unmodified eBPF in the network data plane.⁴ Furthermore, we are interested in evaluating the specific contribution of program warping to FPGA-based eBPF executors, and less concerned with the evaluation of packet processing when using different platforms. However, when looking more generally supporting eBPF on a NIC, some recent commercial NICs that include battery of general purpose CPUs can indeed run unmodified XDP programs.

It should be clear that comparing our program warping prototype with such systems is not generally correct from a technical perspective, since the goals, constraints and scopes of application are too different to devise a fair testing strategy. For instance, a more direct comparison of the packet forwarding data plane component would require an ASIC-based implementation of program warping.

While we are aware of the above, we believe that the comparison may still be useful for practitioners who may be interested in evaluating FPGA NIC solutions vs alternatives. Therefore we decided to at least include such tests in this appendix for the interested reader.

NVIDIA Bluefield2 architecture We tested the XDP programs performance on an NVIDIA Bluefield2 NIC [32] (in NVIDIA terminology, these devices are currently called Data Processing Units, or DPUs). The Bluefield2 combines two main subsystems: a switching data plane based on the Mellanox ConnectX6 architecture; and a battery of 8 general purpose Arm A72 CPUs running at up to 2.75GHz. The ConnectX6 receives the packets from the network ports and can forward them directly to the host system, like a regular NIC,

⁴In fact, Netronome SmartNICs [31] support eBPF, but only in a limited form, and therefore packet processing programs need to be rewritten for the specific Netronome's capabilities.

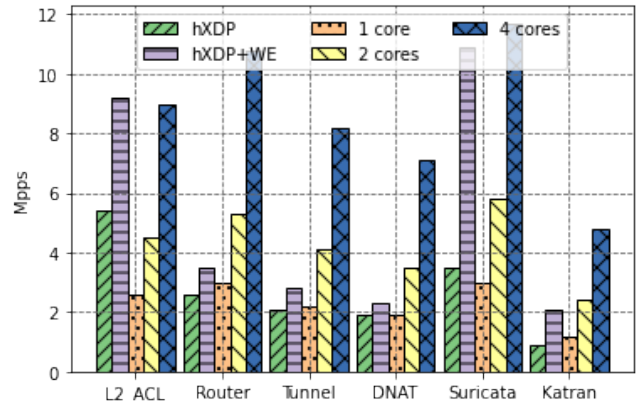

Figure 7: Forwarding throughput for the applications described in Section 6, when running on hXDP, hXDP+Warp Engine, and on 1-4 cores of an NVIDIA Bluefield2's CPUs.

or it can re-direct them to the Arm CPUs. Here, further processing can happen, and the packets can be either *consumed* locally, or sent back once more to the ConnectX6, to be finally delivered to the host system or to the network port.

Experiments We use the experimental setup, applications and testing strategy described in Section 6 to evaluate the packet forwarding performance of the Bluefield2, when using the Arm CPUs. Figure 7 shows the results.

Like already explained in Section 6, we report the results only for a subset of the application paths. For Router, Tunnel and DNAT, the hXDP+Warp Engine combination achieves a higher throughput than an Arm core clocked at over 10x the hXDP clock frequency. For Katran, our prototype is close to the performance provided by two cores. Finally, in the case of L2_ACL and Suricata, the hXDP+Warp Engine achieves a forwarding throughput roughly equivalent (or close) to 4 Arm cores instead.

These results show that in favorable cases program warping can indeed boost the performance of an FPGA-based processor to match that of several hardcoded cores running at much higher frequency. This suggests that a practitioner will require a careful workload analysis if the choice of an FPGA NIC is not mandated by other deployment requirements⁵, since the performance is use case dependent. In any case, program warping provides a viable solutions to run eBPF software packet processing in environments where an FPGA NIC is required.

⁵Requirements may not be necessarily related to the need of hosting FPGA-based accelerators. They may also include considerations on power consumption and type of board cooling.

NVMe SSD Failures in the Field: the Fail-Stop and the Fail-Slow

Abstract

NVMe SSD has become a staple in modern datacenters thanks to its high throughput and ultra-low latency. Despite its popularity, the reliability of NVMe SSD under mass deployment remains unknown. In this paper, we collect logs from over one million NVMe SSDs deployed at Alibaba, and conduct extensive analysis. From the study, we identify a series of major reliability changes in NVMe SSD. On the good side, NVMe SSD becomes more resilient to early failures and variances of access patterns. On the bad side, NVMe SSD becomes more vulnerable to complicated correlated failures. More importantly, we discover that the ultra-low latency nature makes NVMe SSD much more likely to be impacted by fail-slow failures.

1 Introduction

NVMe SSD is now the new favorite of modern data centers. With a performance specification of up to 6GB/s bandwidth and microsecond-level latency, NVMe SSD serves as a strong performance upgrade to its SATA-based peers [8, 18, 29–31].

Apart from the performance, the reliability of any hardware under mass deployment is of great concern [3, 5–7, 10, 14, 38, 40, 42, 45]. While there is a spate of work covering the failure characteristics of SATA SSDs in the field [34–36, 41, 47], their findings may not be conclusive for NVMe SSD.

First, with a low-latency interface, NVMe SSD can be especially *prone* to fail-slow failure (aka. gray failure [17, 21, 25, 26, 48]). In a nutshell, the NVMe SSD fail-slow failure causes a drive to exhibit abnormal performance slowdown (e.g., high latency under normal traffic). Unlike SATA SSD, where fail-slow failure may be masked by the relatively high latency (>100μs), NVMe SSD can be easily impacted due to its ultra-low latency nature (~10μs) [23, 27, 28].

Moreover, the NVMe SSD is not just the SATA SSD with an interface upgrade. Instead, the internal architecture of NVMe SSD has gone through considerable changes. An outstanding example is the wide adoption of 3D-TLC NAND in NVMe SSD for larger capacity. Compared to MLC, the denser bits per cell (i.e., TLC) shows lower reliability and

the vertical stacking (i.e., 3D flash) can exhibit disparate behaviors or even opposite patterns (e.g., lower error rate under higher temperatures [32]). Also, the vendors have integrated a series of techniques to improve the overall reliability in NVMe SSD, such as Redundant Array of Independent NAND (RAIN) or Low-Density Parity-Check code (LDPC) [43, 50]. Unfortunately, with no large-scale NVMe SSD fail-stop study available at the moment, the influences of recent advancements remain unknown.

In this paper, we study the fail-stop and fail-slow failures of NVMe SSDs deployed at Alibaba. Specifically, we collect and analyze device logs (i.e., SMART [11]), runtime logs (i.e., *iostat*), and failure tickets from over one million NVMe SSDs¹. Throughout the study, we set our analysis into the context of previous studies to help various parties of interest get a clear picture of NVMe SSD reliability, including the improving and deteriorating failure patterns of fail-stop failures and the characteristics regarding the fail-slow failures.

We start our study by plotting and analyzing the baseline statistics (§3) of the NVMe SSDs, including the drive characteristics (e.g., manufacturer and model), usage characteristics (e.g., power-on time), and health metrics (e.g., annual replacement rate). Then, we comb through the dataset against different impact factors such as age and write amplification (§4). Finally, we lay a special focus on the fail-slow failures (§5), where we rigorously identify the fail-slow drives and perform extensive analysis. Altogether, we obtain 10 major findings and we list the highlights as follows:

- Infant mortality (failures occurring soon after deployment), a concerning failure trend in SATA SSD [35], is not outstanding in NVMe SSD. For nearly all of our models, the failure rate in the first three months is equivalent to or even less than that from later periods.
- High Write Amplification Factor (WAF), unlike SATA SSD [36], is no longer closely correlated with failures. Interestingly, NVMe SSD with low WAF (WAF≤1) exhibits 2.19× higher ARR than high-WAF ones.
- Co-located (i.e., intra-node/rack) NVMe SSD failure becomes more temporally correlated. For example, compared to SATA SSD, NVMe SSD correlated failure increases up

*Equal contribution.

†Corresponding authors.

¹We release our dataset at <https://tianchi.aliyun.com/dataset/dataDetail?dataId=128972>.

to $14.69\times$ and $1.78\times$ in intra-node/rack scenarios, respectively.

- The fail-slow failure is a widespread and severe problem for NVMe SSD. On average, 1.41% of NVMe SSDs are infected within four-month monitoring, which is $6.05\times$ that of HDD. Besides, fail-slow NVMe SSD could degrade to SATA SSD or even HDD performance.
- The NVMe SSD fail-slow failure does not correlate with SMART attributes, and rarely (0.22% of the fail-slow drives) transits to fail-stop failures.

We conclude this paper with the limitation of this study (§6), the related work (§7) and a short conclusion (§8).

2 Background

2.1 System Architecture

The NVMe SSDs, in our study, come from multiple IDCs (Internet Data Centers) across the globe. An IDC usually hosts dozens of storage clusters. The clusters are homomorphic with each running an HDFS-like distributed file system (DFS). Each cluster owns several to tens of racks and each rack includes up to 48 nodes. All NVMe SSDs in our study come from the all-flash-configuration nodes that contain 12 NVMe SSDs (not RAIDed) for data storage (not hosting OS).

2.2 Drive Model & Workload

Our candidate SSDs are all enterprise-level. The earliest model was deployed around May 2015, while the latest model is from July 2019. We introduce the details in §3.

The SSD fleet serves a total of 7 services, including block storage, object storage, big data, buffering, log, streaming, and query. Each service spans across several dedicated clusters. For confidentiality, we do not share the numbers of SSDs or their distribution under each service. Still, we study the influences of workload under controlled-variable experiments.

2.3 Data Collection

| Data | Span | Entry |
|-----------------|-----------------------|-------|
| SMART Logs | 2019-11-04~2020-11-14 | ~1.8M |
| Perf. Logs | 2020-11-16~2021-03-05 | ~84M |
| Failure Tickets | 2019-11-04~2020-11-02 | ~20K |

Table 1: Data collection period (§2.3).

SMART logs. SMART is a set of attributes widely adopted by vendors and administrators to evaluate the reliability and performance of drives [11]. In our clusters, the reportings of SMART attributes are collected on a daily basis. Readings of the metrics can be either cumulative (e.g., number of media errors) or instantaneous (e.g., temperature). In practice, vendors may not necessarily follow the exact counting or reporting mechanism. Therefore, we standardize the numbers based on the manufacturer manuals.

Performance logs. A major subset of our clusters is equipped with node-level daemons to monitor and record the `iostat`, a Linux kernel performance log. The `iostat` includes vital statistics of storage devices, such as latency, IOPS and throughput. Currently, the daemon runs 3 hours a day (from 9 PM to 12 AM) and only records the average `iostat` values of each monitoring window (15 seconds long). Within the three hours, the traffic is relatively stable (around 70% peak traffic) and dominated mainly by internal workloads and large external clients (i.e., less burst traffic).

Failure tickets. Every node in our clusters has set up a daemon to monitor and report fail-stop failures. Upon reporting, a failure ticket would be generated (and manually checked by engineers), containing basic information of the victim drive (e.g., model and hostname) and the timestamp. Around 35% of our nodes also record an error code, detailing the direct symptom of failure (see Table 3 in §3.1). Upon failures, based on the symptoms, drives would be repaired online (e.g., `fsck`) or directly put offline for replacement (e.g., drive lost).

2.4 Methodology Correctness

To ensure sound and generalizable conclusions, we adhere to the following principles and measures throughout the study.

First, our study methodology (similar to [19, 34, 36, 41, 47]) starts with a general and extensive comparison to identify outstanding dominant factors. If high-level observation is fruitless or suspicious (e.g., spurious correlation led by interdependence between different factors as noted in [41]), we would then perform fine-grained controlled variable experiments (e.g., conditioned on workloads, drive models, drive age and the total bytes written) to unravel the underlying root causes and actionable advice for practitioners if any.

Second, we pre-screen the raw datasets to avoid bias (e.g., higher average) led by outliers (e.g., overflowing SMART values, NULL `iostat` recordings). Note that on-site engineers have manually verified all failure tickets before this study. In total, we have dropped around 5.8% and 1.5% untrustworthy records from SMART logs and `iostat`, respectively. Moreover, for generalizability concerns, we also exclude drive models with a smaller population (less than 1K) from the study. Note that different suppliers may register a model by different names, but we treat them as the same one here.

Third, we carefully choose statistical instruments to identify and verify the potential patterns in the NVMe SSD failures. Our rationale is that either such techniques or thresholds have been applied in previous studies, or clear documentation indicates the techniques can be used in the targeted scenarios.

3 Baseline Statistics

3.1 Dataset Overview

SMART logs. We begin by presenting the baseline statistics in Table 2, where the dataset is grouped into three categories: Basic Information, Usage Characteristics, and Health Metrics.

| Basic Information | | | | | Usage Characteristics | | | Health Metrics | | | | |
|-------------------|-----------|--------|-------------|-----------|-----------------------|-----|------|----------------|-------------|------------|-----------|---------|
| Model | Cap. (GB) | NAND | Lith./Layer | Total (%) | Drive Years | OP | WAF | Crit. Warn. | CRC Err. | Media Err. | P/E Err. | ARR (%) |
| I-A | 800 | MLC | 15nm | 0.1 | 3.32 | 28% | 1.69 | 0.0015 / 0 | 1439.46 / 0 | 0 / 0 | 0 / 0 | 0.34 |
| | 2000 | MLC | 15nm | 0.8 | 3.07 | 2% | 2.05 | 0.027 / 0 | 759.73 / 0 | 3.52 / 0 | 0 / 0 | 0.69 |
| | 3840 | MLC | 15nm | 0.1 | 2.87 | 7% | 0.84 | 0.0025 / 0 | 3091.59 / 1 | 0 / 0 | 0 / 0 | 0.78 |
| I-B | 1600 | MLC | 15nm | 0.7 | 2.73 | 28% | 1.82 | 0.011 / 0 | 0 / 0 | 0.01 / 0 | 0 / 0 | 1.12 |
| | 3200 | MLC | 15nm | 0.1 | 2.99 | 28% | 1.86 | 0.16 / 0 | 0 / 0 | 759.81 / 0 | 0 / 0 | 2.34 |
| I-C | 4000 | 3D-TLC | 64L | 0.1 | 0.46 | 2% | 1.04 | 0 / 0 | 0 / 0 | 0 / 0 | 0 / 0 | 0.66 |
| II-A | 1920 | MLC | 20nm | 0.5 | 3.44 | 7% | 3.68 | 0.052 / 0 | 59.46 / 0 | 0 / 0 | 1.70 / 0 | 0.77 |
| II-B | 800 | MLC | 20nm | 0.7 | 3.60 | 28% | 7.82 | 0 / 0 | 52.90 / 0 | 0 / 0 | 3.10 / 0 | 0.49 |
| | 1600 | MLC | 20nm | 1.3 | 3.63 | 28% | 7.97 | 0 / 0 | 43.52 / 0 | 2.69 / 0 | 5.80 / 0 | 0.63 |
| II-C | 960 | 3D-TLC | 32L | 3.4 | 2.55 | 7% | 3.62 | 0 / 0 | 1572.77 / 0 | 0 / 0 | 0.79 / 0 | 0.52 |
| | 1920 | 3D-TLC | 32L | 1.8 | 2.50 | 7% | 2.88 | 0.0017 / 0 | 849.99 / 0 | 0.49 / 0 | 1.60 / 0 | 0.79 |
| | 4000 | 3D-TLC | 32L | 5.5 | 2.39 | 2% | 3.36 | 0.00079 / 0 | 957.86 / 0 | 0.34 / 0 | 3.60 / 1 | 0.64 |
| II-D | 960 | 3D-TLC | 64L | 4.9 | 1.47 | 7% | 2.45 | 0.00026 / 0 | 38.66 / 0 | 1.45 / 0 | 0.38 / 0 | 0.26 |
| | 1920 | 3D-TLC | 64L | 8.4 | 0.97 | 7% | 2.37 | 0.00031 / 0 | 54.56 / 0 | 0.45 / 0 | 0.45 / 0 | 0.56 |
| | 3840 | 3D-TLC | 64L | 45.3 | 0.69 | 7% | 1.96 | 0.000038 / 0 | 32.72 / 0 | 5.53 / 0 | 0.66 / 0 | 1.12 |
| II-E | 370 | NEW | 20nm | 0.5 | 1.24 | 0% | - | 0 / 0 | 72.05 / 0 | 0.71 / 0 | 0 / 0 | 1.40 |
| | 750 | NEW | 20nm | 0.7 | 0.18 | 0% | - | 0 / 0 | 38.92 / 0 | 16.27 / 0 | 0 / 0 | 3.27 |
| III-A | 3200 | 3D-TLC | 48L | 0.3 | 2.65 | 28% | 2.59 | 0 / 0 | 19.39 / 0 | 45.28 / 0 | 0.28 / 0 | 2.31 |
| III-B | 960 | 3D-TLC | 48L | 3.4 | 1.96 | 7% | 3.34 | 0.0038 / 0 | 296.41 / 0 | 2.29 / 0 | 30.00 / 0 | 0.60 |
| | 1900 | 3D-TLC | 48L | 7.4 | 1.73 | 7% | 2.78 | 0.0080 / 0 | 263.04 / 6 | 0.82 / 0 | 69.00 / 0 | 0.69 |
| | 3800 | 3D-TLC | 48L | 9.9 | 1.93 | 7% | 1.87 | 0.010 / 0 | 469.66 / 6 | 1.81 / 0 | 67.00 / 0 | 1.13 |
| III-C | 960 | 3D-TLC | 64L | 4.1 | 0.45 | 7% | 3.96 | 0.0023 / 0 | 124.55 / 0 | 0.02 / 0 | 5.30 / 0 | 0.49 |

Table 2: Baseline statistics of our drives (§3). The table shows the summarized statistics of NVMe SSD fleet. *Cap.:* capacity; *NAND:* flash architecture; *Lith./Layer:* lithography or numbers of stacking layers; *OP:* Over-Provisioning rate; *WAF:* Write Amplification Factor; *Crit. Warn.:* critical warning; *P/E Err.:* program/erase error. In Health Metrics, the two values separated by a slash refer to mean and median values, respectively.

In Basic Information, we name the drive models as manufacturer-model and use the alphabetic order to refer to the generations of a manufacturer (e.g., I-A stands for the earliest model from manufacturer I). Each model can be further specified by capacities (i.e., Cap. column) and NAND architecture (i.e., NAND column). We mark the planar chips with their lithography (e.g., 15nm for I-A) and the 3D chips with their vertical stacking layers (e.g., 64-layer for I-C). II-E is a unique case as it adopts a novel (neither planar nor 3D stacking) cell, thus named NEW (for anonymity). Finally, we list each model’s relative population (i.e., Total%).

The Usage Characteristics describes the high-level administrative information. The first column is the average power-on time in terms of years. The second and third columns respectively present the over-provisioning rate (i.e., OP) and the calculated average Write Amplification Factor (i.e., WAF). WAF is calculated by dividing the number of NAND writes by the number of logical writes. Both numbers are reported by the SSD SMART attributes.

Last, we cover five primary reliability-related metrics.

- *Critical Warning*, introduced by NVM Express [20], indicates that the drive may have serious media errors (i.e., in read-only or degraded mode), possible hardware failures, or exceeding temperature alarm threshold.

- *CRC Error* refers to the number of transmission errors (e.g., the faulty interconnection between the drive and the host).
- *Media Error* refers to the number of data corruption errors (i.e., unable to access stored data in flash media).
- *Program/Erase Error* refers to the number of flash cell programming errors (e.g., unable to program flash cells from a block that is about to be garbage collected during copyback).
- *Annual Replacement Rate (ARR)* is the number of device failures divided by numbers of device years, reflecting the general reliability of drives (a common standard [34, 41]).

Note that readings of the first four health metrics are heavily biased where zeros account for an absolute majority (e.g., 99.97% for critical warning) of valid recordings. Hence, we list both average and median values (i.e., average/median).

Failure tickets. A subset (around 35%) of our drives details the direct cause upon failure reporting. Here, we present the distribution of their symptoms in Table 3. There are a total of five failure symptoms. I/O failure refers to a drive that fails to perform a read/write request. The Link failure indicates either a connection error during the PCI-e transmission or an abnormal bandwidth. The Lost failure refers to a functioning drive to become unfound. The Boot failure describes a drive that fails to initiate (e.g., mounting file system). The Thres. failure refers to one or more SMART attributes to have reached the

| Type | Distribution Statistics | | | | |
|--------|-------------------------|-------|-------|--------|-------|
| | Dist. | ARR | ARR_M | ARR_3D | ARR_N |
| I/O | 49.55% | 0.40% | 0.14% | 0.42% | 1.07% |
| Link | 11.07% | 0.09% | 0.01% | 0.10% | 0.10% |
| Lost | 5.65% | 0.05% | 0.06% | 0.04% | 0.01% |
| Boot | 19.59% | 0.16% | 0.30% | 0.14% | 0.39% |
| Thres. | 14.15% | 0.11% | 0.20% | 0.10% | 0.10% |

Table 3: Failure symptom distribution (§3.1). *Dist.*: distribution; *ARR*: overall ARR; *ARR_X*: ARR of drives under different flash architecture; *I/O*: read/write failure; *Link*: connection failure; *Lost*: drive unfound; *Boot*: booting failure; *Thres.*: SMART value over a pre-defined threshold.

pre-defined threshold(s). For each type of failure, we present its distribution (Dist. column) along with the corresponding ARRs in all NVMe SSDs (ARR), MLC-based (ARR_M), 3D-TLC (ARR_3D), and NEW-NAND ones (ARR_N).

3.2 High Level Observations

Based on Tables 2 and 3, we now associate drive characteristics with health metrics to get a high-level understanding of the NVMe SSD fail-stop failures. Note that, even for the same model, the drive population can be a diverse mix of model and usage characteristics (e.g., NAND type, age, and total bytes written). We have further verified our observations through controlled-variable experiments on such impacting factors.

NVMe SSD vs. SATA/SAS SSD. The ARR of NVMe SSD in our dataset is much higher than that of SATA/SAS SSD from Netapp’s enterprise storage systems [34]. We perform a t-test on both sets of ARRs and the corresponding p-value is equal to $3.554e-07$. The average and median ARR of our NVMe SSD are 0.98% and 0.69%, which are $2.77\times$ and $2.83\times$ higher than those of SATA/SAS SSD respectively (i.e., 0.26% and 0.18% calculated from Table 1 in [34]). We obtain similar results as we further break down the SSD population by NAND types and lithography. Regarding Alibaba’s data centers [19], the trend persists except for two models (i.e., C1 and C2 from Table 1 in [19]).

Moreover, we also compare the failure symptom distribution between NVMe SSD and SATA SSD (see Table 3 in [47]). We observe radical changes as I/O error becomes far more prevalent in NVMe SSD (accounting for 49.55%) while Lost error (i.e., drive unfound) is no longer dominant (i.e., 5.65% in NVMe SSD vs. 53.7% in SATA SSD).

Drive capacity. Within the same drive family, the average P/E errors and ARR are positively correlated with the capacity. For example, in the II-D drive family, as the capacity increases, the average P/E error rises from 0.38 to 0.66 and the ARR surges from 0.26% to 1.12%. This is understandable as drives with larger capacity are more likely to be accessed, thereby increasing the chances of suffering program errors.

NAND type. In our dataset, we find that the ARR of 3D-

TLC drives is slightly lower than that of MLC drives, while in SATA SSD [34], the trend is reversed. The ARR of our MLC drives varies from 0.34% to 2.34%, while that of 3D-TLC SSD is from 0.26% to 2.31%. However, we notice that drives with NEW NAND architecture (i.e., II-E family) exhibit around $1.61\times$ and $1.87\times$ higher average ARR than those of MLC and 3D-TLC drives, respectively (the p-values are equal to $2.065e-02$ and $4.351e-03$). Table 3 further demonstrates an ARR breakdown of failure symptoms among different NAND chips. For NEW-based SSD, the main culprits of its high ARR are the I/O and booting failures.

4 The Fail-stop

Now, we present the three major changes in failure patterns in NVMe SSD. For each aspect, we start with existing patterns in SATA/SAS SSD. We then study the differences in NVMe SSD using a similar setup and further verify our findings under a series of controlled-variable experiments.

4.1 Infant Mortality

Finding 1. *Infant mortality, a notorious failure trend in hardware early deployment period, is not notable in NVMe SSD.*

Existing patterns. The Bathtub Curve [40] is a classic depiction of hardware failure variances through time. Generally, there are three main phases: infant mortality, stable (aka. useful-life) and wear-out period. Previous SATA SSD studies suggest that flash drive also follows this trend [35] (i.e., with an early detection phase followed by the bathtub curve).

Difference in NVMe SSD. For NVMe SSD, we are interested in whether such observation still holds. Here, we adopt the monthly failure conditional probability (FCP) to demonstrate the failure trend (i.e., the same metric as in Section 5.1 of [34]). The FCP is calculated as the number of drives to be replaced that month divided by the number of drives surviving that month. In Figure 1, we present a comparison between the six most popular drive families covering varying NAND architectures (i.e., 15-20nm MLC, 32-64 layers 3D-TLC, and the NEW). Throughout the paper, error bars refer to 95% confidence intervals with bootstrap methods [12] (2,000 iterations). In Figure 1, to calculate the error bar of FCP in month x (with N drives surviving month $x-1$), we create 2,000 random samples of FCPs; in each sample, the FCP is calculated based on a randomly-chosen set of N drives (i.e., sampling with replacement). Finally, we calculate the 95% confidence interval based on these 2,000 samples of FCPs as the corresponding error bar.

Should the NVMe SSD still follow the bathtub curve, we shall see the FCP, starting from a high value (i.e., the infant mortality), quickly decreases to a stable range (i.e., the useful life) until surging in the wear-out period. However, from visual inspection, we discover that most drive families do not have outstanding infant mortality during early periods. We further calculate the average FCP under various periods (e.g., 1st to 3rd month and the most recent three months).

Figure 1: Failure trend (§4.1). The figures present the Failure Conditional Probability (%) vs. drive’s deployed time in months in 6 drive families. The dashed line indicates the average value within each figure. Error bars throughout the paper refer to 95% bootstrap confidence intervals [12] (2,000 iterations).

As a result, the early period (i.e., the first three months) has equivalent or even lower FCP than the later periods. For example, in I-A, the first three months yield an average FCP of 0.02%, whereas the average FCPs of the next 9 months (months 4-12) and most recent three months are 0.05% and 0.35%, respectively.

Validity analysis. Next, we explore the reason behind this reliability improvement. First, it is unlikely that the stress tests weed out the faulty drives before deployment. Stress tests are usually short (up to one week) and thus not enough for drives suffering infant mortality (the period lasts for 12-15 months long [35]). Second, we exclude the possibility of external impacts (e.g., uneven distribution of workloads and drive age, if any) using two-sided t-tests. Then, we focus on the internal aspect by studying the SMART attributes variances over time. Here, for both II-D and III-B in Figure 2, nearly all health-related metrics experience the infant mortality as they start with a much higher value and then decrease to a stable range over time. Other drive families, in general, also follow this trend. Note that the values in Figure 2 are normalized to the lowest point on each curve and reported in logarithmic reporting. This indicates that NVMe SSD still

Figure 2: SMART in early age (§4.1). The figures present the average number of SMART-recorded errors per month during the first 15 months of deployment in two major drive models. Note that the numbers are normalized to the lowest point on each curve.

accumulates a large number of errors during the early period. Therefore, we assume it is likely that the improvement of FTL error handling makes the NVMe SSD more resilient in the early periods.

Operational advice. We believe the recent advancement in failure handling has set the NVMe SSDs free from suffering infant mortality. This can serve as a relief signal for the supply chain and the on-site administrators as previous practice usually demands that the cloud operators stockpile extra pieces before initial deployment.

4.2 WAF

Finding 2. NVMe SSD becomes more robust to high write amplification ($WAF > 2$), but extremely low write amplification ($WAF \leq 1$) is still rare-but-deadly.

Existing patterns. Write amplification is a common phenomenon in SSD I/O where the logical writes incur extra data to be written to NAND due to SSD internal operations (e.g., garbage collection and alignment). A higher write amplification factor (i.e., NAND writes size divided by logical writes size) therefore indicates a more random and small-writes-dominant workload. To overcome this disadvantage, manufacturers often use write compression techniques to combine small or buffer repeated writes [9, 46, 49].

Previously, a large-scale SATA SSD failure study by Microsoft pointed out that higher WAF ($WAF > 2$) incurs more SSD failures (i.e., Section 3.5.1 of [36]). Moreover, they suggest that the write compression technique can be damaging where drives with less-than-one WAF have failure rates similar to those with a higher-than-two WAF (see Figure 11 in [36]).

Difference in NVMe SSD. To avoid bias led by model characteristics, we conduct a comparative study within each model family. For each drive family, we first place SSDs into different buckets by WAF with a step of 0.5. Then for each bucket, we calculate its corresponding ARR. Since the 95th percentile of WAF in our entire fleet is around 4, the last bucket includes

Figure 3: ARR under different WAF levels (§4.2). The grey dashed line indicates the average value within each figure. “[1]”: the bucket includes no drives; “[2]”: the calculated ARR is zero (i.e., no failed drives). The first buckets of III-B and III-C are overflowed ($>5\%$).

drives with WAF above 4. The $WAF \leq 1$ bucket contains drives significantly influenced by the write compression technique.

Figure 3 presents the correlation between WAF and failure rates among eight popular drive families, covering different types of NAND and manufacturers. Here, we make two observations. First, for WAF higher than one, we do not observe a strong positive correlation between WAF and ARR in most drive families (the II-D drive family is considered an exception). A set of Spearman’s Rank Correlation Coefficient tests [44] further statistically confirm our hypothesis. This indicates that NVMe SSD is less affected by random small writes (a major cause for high write amplification). Second, we observe that, for drives with low WAF (i.e., $WAF \leq 1$), their failure rates are still relatively high. On average, these low-WAF drives can have a $2.19\times$ higher ARR rate than average.

| Time | Type | SATA SSD | NVMe SSD | Hypo. |
|------------|-----------|-------------------------|--------------------------|-------------------------|
| Total | node rack | 4.5-73.7% 28.6-91.4% | 70.6-96.6% 79.4-97.6% | 0.04-9.0% 27.8-77.4% |
| (0, 1min] | node rack | 0.8-24.7% 1.7-27.2% | 1.1-17.9% 1.3-17.9% | 0% 0% |
| (1d, 1mon] | node rack | 1.1-39.4% 6.5-47.9% | 14.3-57.5% 15.5-57.2% | 0.01-1.1% 2.9-10.0% |

Table 4: Intra-node/rack failure distributions across drive types (§4.3). The table presents the relative percentage of intra-node and intra-rack failures in SATA SSD from a previous study [19], our NVMe SSD fleet, and a hypothetical setting where failures are independent of time and location.

An extreme example is the III-B drive family (lower left in Figure 3), where low-WAF drives are $6.18\times$ more likely to fail than average. Fortunately, we discover that these low-WAF drives usually occupy only a small proportion (e.g., only 0.09% in III-B). Even for I-A-3840 (i.e., having an average WAF of 0.84), we argue that low-WAF drives can be easily singled out with simple SMART attributes calculation for close monitoring or reallocation.

Validity analysis. Many factors (e.g., workloads, age, wear, and drive model) can influence both the WAF and reliability. To verify our finding, we further conduct a series of experiments by controlling the above variables (not shown due to space limitations). Our evaluation further confirms that none of the factors influences our finding. Therefore, we conclude that, in NVMe SSD, while the low WAF may still be deadly, the high WAF is no longer concerning.

4.3 Intra-node/rack Failures

Finding 3. Spatially correlated (intra-node/rack) NVMe SSD failures are temporally correlated in the long-term span (i.e., 1 day to 1 month), but no longer prevalent in the short span.

Existing patterns. Correlated drive failures are notorious for their cascading impact on the reliability of the entire distributed system (e.g., reduced redundancy) [2, 15]. According to a previous study in Alibaba (i.e., Finding 5 of [19]), a non-negligible proportion (i.e., up to 34.3% and 44.2%) of SATA SSD spatial-correlated (intra-node/rack) failures can also be temporal-correlated within a short span (i.e., at most one minute apart), posing a critical challenge to the overall stability.

Difference in NVMe SSD. To study whether such a correlated pattern still plagues the NVMe SSD fleet, we further check the intra-node/rack failure time intervals in our datasets. Here, to be consistent with the previous study [19], we reuse the Relative Percentage of Failures (RPF) to calculate the likelihood of correlated failures. In RPF, the numerator is the number of the sets of failures that occur between a specific period (e.g., 0 to 1 minute). The denominator is the sum of all failures of a particular drive model. Note that, in RPF, the same failure can be counted repeatedly as a member of

Figure 4: Intra-node/rack failure distributions across drive models (§4.3). The figures present relative percentage of intra-node and intra-rack failures for each drive model. Note that stacked bars can reach above 100% because failures could be counted multiple times into different buckets.

different correlated failures sets. For example, consider three failures, say A, B, and C, all occur within one minute inside the same node. Then there are three sets of correlated failures (i.e., [A,B], [B,C], and [A,C]), thus yielding an RPF of 100%.

In Table 4, we list the RPF from the previous study (i.e., SATA SSD column) and ours (i.e., NVMe SSD column). We make the following observations. First, the accumulated RPFs (i.e., Total row) across all NVMe drive models are substantially higher, with an increase up to $14.69\times$ and $1.78\times$ for intra-node and intra-rack scenarios, respectively. The corresponding t-tests return p-values equal to $6.322e-06$ and $1.881e-04$.

Second, unlike SATA SSD (mostly correlated during short intervals), correlated failures in NVMe SSD are commonly observed only in long intervals (i.e., 1 day to 1 month). Here, we use Figure 4 to demonstrate further the distribution of correlated failure intervals among different models on a weekly breakdown of the long intervals (i.e., 1 day to 1 month). In Figure 4, the upper graph shows the distribution of intra-node intervals, and the lower graph shows the intra-rack ones. We denote each interval with a different color (e.g., darkest for the shortest interval). Figure 4 shows the prevalence of long intervals (i.e., the three lightest/top boxes in each bar) in correlated failures. Conversely, short and medium ones (i.e., the three darkest/bottom boxes) on average occupy less than 17.86% (within 1 minute), 15.48% (1-30 min), and 16.25% (30 min to 1 day) of the total RPF.

Validity analysis. Each rack in our setup hosts hundreds of drives. Under such a considerable number, uniformly distributed failures may also co-occur within a rack. To verify that intra-node/rack failures are indeed a result of non-uniformity, we perform a set of hypothetical experiments where drive failures are redistributed to be uncorrelated (i.e., independent of location and arrival time). First, for each drive model, we sample without replacement to get a new batch of drives and mark them as “failed” drives. Second, we assign a random timestamp from 2019-11-04 to 2020-11-02 to each “failed” drive as its failure time (see Table 1). For a fair analysis, we repeat the above procedures 2,000 times and calculate the average RPFs of intra-node/rack failures for each drive model.

In Table 4, we compare the intra-node/rack failure distributions of hypothetical experiments (i.e., Hypo. column) with those of the original setting (i.e., NVMe SSD column). Our observations are as follows. First, intra-node failures under the hypothetical setting are nearly negligible. For example, the accumulated RPFs (i.e., Total row) of intra-node failures are only 0.04-9.0% under the hypothetical setting, whereas those from the original setting (70.6-96.6%) are much smaller (the p-value is less than $2.2e-16$). Second, even though intra-rack failures are non-negligible under the hypothetical setting, their RPFs are consistently smaller than those from the original setting, e.g., with accumulated RPFs of 27.8-77.4% vs. 79.4-97.6% (the p-value is equal to $1.119e-08$). Therefore, the non-uniformity in intra-node/rack failures is significant in our dataset in contrast with the hypothetical setting.

Operational advice. While the decline of closely correlated failures implies a lower risk of experiencing system-wide failures, the surging of long-interval correlated failures still poses a pressing threat. An inconvenient fact is that fixing drive failure usually starts with software-based approaches (e.g., data scrubbing and fsck), and such online checking and repairing takes time [16, 33, 47]. In fact, we discover that 43.90%, 14.36%, and 10.90% of the failed drives in our clusters are repaired after one day, one week, and two weeks. Based on our finding, we have refined our operational process by directly putting drives offline upon failures to reduce the chances of suffering long-term correlated failures.

5 The Fail-slow

Apart from the common fail-stop failures, we are also interested in fail-slow failures where drives exhibit performance much less than expected (e.g., considerably high latency under normal traffic). We hypothesize that the ultra-low latency nature of NVMe SSD would make the drive more *susceptible* to fail-slow failures. To verify our assumption, we conducted an extensive study based on the per drive `iostat` traces from more than half a million NVMe SSDs and more than 4 million HDDs during four-month monitoring.

Note that our storage system requires all replicas (three replicas in most cases) ACKed before any write request is

Table 5: Baseline statistics for fail-slow (§5.1-§5.2). The table shows the summarized statistics of fail-slow occurrences under the 5-min to 60-min duration requirements. **Lith./Layer/Type:** lithography, numbers of stacking layers or HDD type; **Event Freq.:** fail-slow event frequency per 1K drives per hour; **Dur.:** average event duration in minutes; **Event Laten.:** average event latency in μs . Note that the SSDs and HDDs under heavy traffic are not included (see §5.1).

returned, while only one ACKed for each read request. Thus, fail-slow failures are more likely to impact the write performance than the read. Such a phenomenon agrees with most known fail-slow cases in practice. Throughout this section, we focus on the write latency where fail-slow failure can be more destructive.

5.1 Identifying Fail-slow Events and Drives

Currently, a subset of our clusters is equipped with daemons to monitor the `iostat` of the deployed drives. Due to capacity limits and performance concerns, the daemon runs 3 hours (9 P.M. to 12 A.M.) each day. It only records the average statistics of each monitoring window (15 seconds in the current setup), thereby yielding 720 records per drive (3 hours divided by 15 seconds) each day.

Methodology overview. We use the following threshold-based approach to identify fail-slow drives (similar to a previous study on SATA SSD and HDD tail latency [21]). The first step is to select suspicious drives with high latencies. Then,

we determine whether the chosen drives are indeed fail-slow by checking the existence of consistent slowdowns.

Identifying suspicious fail-slow drives. In the first step, we observe that the performance (e.g., latency, IOPS, and throughput) records within a cluster generally follow a Positively Skewed Distribution. For example, in one cluster, the median latency is only $49.19\mu s$ while the average latency is $667.85\mu s$. Thus, we can use a latency threshold as $(-\infty, 3rd_quartile + 2IQR)$ to identify the outliers (i.e., slow drives) [39] where the *IQR* (interquartile range) is computed by subtracting the first quartile from the third quartile.

If the 3-hour median latency of a drive is beyond the bar, we mark this drive as a suspicious slow drive. To avoid reporting led by heavy traffic (i.e., false-positive), we also rule out high-latency drives under heavy traffic (i.e., IOPS/throughput is also beyond $3rd_quartile + 2IQR$).

Identifying slowdown events. Note that a suspicious drive may be marked due to transient but time-consuming events (e.g., read retries, unstable connection). Therefore, we further

check whether a suspicious drive has experienced a consistent slowdown event to pinpoint the fail-slow drives. Here, we borrow the idea of measuring slowdown events from a previous SSD performance study [21].

First, we mark the 3-hour `iostat` latency records from the suspicious slow drive and its 11 intra-node peers (12 drives per node) as L_i^k , representing the record i ($i \in \{1, 2, \dots, 720\}$) from drive k ($k \in \{1, 2, \dots, 12\}$). Then, we use RL_i^k (Relative Latency) to indicate the slowdown degree of drive k at record i , formally $RL_i^k = \frac{L_i^k}{\text{median}(L_i^1, L_i^2, \dots, L_i^{12})}$. Then, we formulate an event as $E_{i,j}^k$ by computing the means of RLs of drive k from record i to j , formally $E_{i,j}^k = \text{mean}(RL_i^k, RL_{i+1}^k, \dots, RL_j^k)$.

For an $E_{i,j}^k$ to be considered a fail-slow event, it must satisfy two requirements. First, $E_{i,j}^k$ needs to be larger than an empirical slowdown degree. We set the slowdown degree as 2 (same in [21]), meaning that, during the event, the victim drive is at least twice slower than its peers. Second, we set four minimum spans as 5, 15, 30 and 60 minutes, meaning the $E_{i,j}^k$ should last longer than 20, 60, 120 or 240 records (a record spans 15 seconds).

To sum up, a drive (i.e., NVMe SSD or HDD) is deemed fail-slow if and only if it has a high median latency (i.e., higher than top 0.04% latency variances in the cluster during 3-hour monitoring) and suffers at least one fail-slow event.

5.2 Dataset and High Level Observations

5.2.1 Dataset Overview

In total, we have identified around 5K and 3K fail-slow NVMe SSDs and HDDs, respectively. Table 5 gives an overview of the fail-slow drives and events among the fleets. We use four quadrants to represent the statistics under different requirements (i.e., 5 to 60 min). The upper half of each quadrant includes 8 major NVMe SSD models (named as brand-model-capacity), while the lower includes the three most popular HDD models (H1, H2, and H3) in our clusters.

For each column, we begin by listing the lithography (for planar NAND), layers (for 3D-NAND), or the type (for HDD, i.e., CMR or SMR). Further, we show the percentage of drives that have been identified as fail-slow ones in that model (Slow Drive%). The Event Freq. describes the numbers of events per 1000 drives per hour, reflecting the fail-slow severity in a mid-sized cluster. The following two columns (Duration and Event Latency) show the average fail-slow event duration and average event latency. The final column (Slowdown Ratio) is the ratio of average event latency to average latency of peer drives (i.e., healthy drives from the same node) during the event. The last row of each sub-quadrant is the average value for each category (i.e., SSD or HDD).

5.2.2 SSD vs. HDD

Finding 4. *Compared to HDD, fail-slow failure in NVMe SSD is much more widespread and frequent, and can degrade the drive to SATA SSD or even HDD level performance.*

We start with the differences between NVMe SSDs and HDDs. First, we observe the disparity between HDD and SSD in slow drive popularity (i.e., Slow Drive %). Comparing the average row in each quadrant reveals that slow drives are $6.05\times$ (i.e., 1.41% to 0.20% in the 5-min quadrant) to $51\times$ (0.52% to 0.01% in the 60-min quadrant) more common in SSDs. Similarly, we also observe that the fail-slow occurrences (i.e., Event Freq.) are much more frequent in SSDs, ranging from $18.59\times$ (5-min) to $68.50\times$ (60-min).

Regarding the event duration, the difference varies. On average, the SSD event lasts up to 55% longer in the first three quadrants, but the trend reverses as the HDD event costs 5% more time in the 60-min quadrant. This indicates that fail-slow events in NVMe SSD are relatively short-termed.

Moreover, while models like II-D-1920 and III-B-1900 still deliver relatively satisfying performance, fail-slow NVMe SSDs usually degrade to SATA-SSD-level latency (i.e., having an average event latency around $160\mu\text{s}$, see average rows of event latency from 5-min to 60-min). Even worse, our evaluation shows that the top 1% slowest events in several NVMe SSD models deteriorate to an average latency of around 22ms, an unsatisfying performance even for HDD.

The comparisons of slow drive popularity, event frequency, and performance prove that the NVMe SSD is indeed widely plagued (1.41% affected under 5-min requirement) and severely impacted ($\sim 160\mu\text{s}$ average event latency) by fail-slow failure. Recall that the dataset comes from only three hours of monitoring per day for four months. Plus, all of our models are enterprise-level, and we have already excluded SSDs under heavy traffic. Therefore, we expect the annual fail-slow drive rate to be higher and fail-slow occurrences more frequent in the field.

Operational advice. Experiencing widespread and severe fail-slow faults can be particularly harmful to NVMe SSDs as performance-sensitive jobs are usually placed on them. However, simply putting all fail-slow drives offline can be unacceptably expensive. Recently, we have been experimenting with a “three strikes” approach to tackle the suspiciously slow drives. Specifically, the first time a drive is diagnosed with fail-slow failure, we would clean the drive’s data and deploy it again as a new drive. In the second time, we would fully flush the drive with zeroes, reformat and redeploy it. A third timer would be directly put offline for replacement. Unfortunately, we have just deployed this strategy and do not have enough samples for analysis.

Root cause. We have sent 100 slowest SSDs (around the top 2% of the identified slow drives with an average event latency of 4.4 ms) back to vendors for repair. The results show that 33 of them have bad capacitors, causing the malfunctioning buffer and thus the high latency. 46 of them contain bad chips and the root causes of the rest remain unclear.

5.2.3 Differences between SSD models.

Finding 5. *The manufacturer is a dominant factor of fail-slow*

Figure 5: CDF of fail-slow event reoccurrence (§5.2). The figures present the distribution of event reoccurrence for two models under four duration requirements.

drive population in NVMe SSD.

Now, we dig deeper by focusing on the fail-slow distribution differences between SSD models. First, we look at the influences of the manufacturers. Our dataset includes three manufacturers (i.e., I, II, and III). For slow drive percentage, there is a clear order (i.e., manufacturer I followed by III and II) across the four quadrants. Even the highest value of III (e.g., 3.04% of III-B-1900 in 5-min quadrant) is well behind that of the I’s model (i.e., 4.44% of I-A-2000), which also applies to the comparison between III and II. However, we do not observe visible patterns for the event duration, event latency, and slowdown ratio.

Finding 6. Higher fail-slow drive popularity does not always lead to a higher fail-slow event frequency.

Moreover, we notice a seemingly counter-intuitive pattern. One may assume a higher fail-slow drive percentage leads to a higher event frequency. While this hypothesis holds in the longest duration requirement (60-min quadrant), we find many counter-examples among shorter ones (e.g., II-A-1920 and II-C-1920 in 5-min quadrant).

A possible explanation is that under a shorter duration requirement, there are more drives with multiple events, resulting in a small slow drive percentage with high event frequency. Here, we further verify this assumption by using Figure 5, a CDF of events per drive under different duration requirements. We can clearly see that drives under shorter durations accumulate more events than those under longer durations.

5.3 Correlating Factors

In this section, we conduct an extensive study on fail-slow failures versus various correlating factors (i.e., drive age, workload and SMART attributes).

5.3.1 Drive Age

Finding 7. Fail-slow drive population and event frequency are strongly correlated with age, but only for old (power-on time > 41 months) NVMe SSDs.

Age is widely known for its significant impact on SSD fail-stop failures [34, 35, 41]. We correlate fail-slow metrics with drive power-on time to see the significance of age here.

We first place all fail-slow drives into monthly buckets

Figure 6: Fail-slow drive percentage across time (§5.3.1). The figures show the percentage of fail-slow drives per month under the 5-min and 60-min duration requirements. The dashed line indicates the average value within each figure.

(e.g., bucket-1 includes fail-slow drives with power-on time between 0 to 1 month). Note that for a drive with multiple event occurrences (e.g., fail-slow events in both 34th and 35th months), we put the drive to the earliest bucket (i.e., 34th-month bucket). Then we calculate the fail-slow drive percentage for each bucket by dividing the numbers of fail-slow drives against the numbers of drives of the same age.

Figure 6 demonstrates the population variances along time under the 5-min (left) and the 60-min (right) requirements where the horizontal dashed line is the average. We can see that the population, in both scenarios, oscillates around the average value at first and then start to surge in the final months. Further, a Spearman’s Rank Correlation Coefficient (SRCC) test [44] reveals that the fail-slow population in old drives (>41 months) is highly correlated with age. Specifically, in the 5-min requirement, the SRCC score for old drives is around 0.92 (way beyond the common threshold for positive correlation, i.e., 0.5). In contrast, the scores from the rest (i.e., younger drives) are close to 0, meaning no correlation. Similar trend exists under 15-min, 30-min, and 60-min requirements.

Next, we adopt similar approaches to measure the correlation between age and other metrics, including event frequency, event duration, and slowdown ratio. We find that the event frequency is similar to the fail-slow population where old drives (i.e., > 41 months) are strongly correlated with age while young drives are not. We do not observe a notable correlation for duration and slowdown ratio, indicating that both metrics remain rather stable throughout the lifecycle.

5.3.2 Workload

Finding 8. The workload can significantly affect various fail-slow characteristics, and heavy traffic workload may have long-lasting impacts on fail-slow occurrences.

Workload is also a well-known impact factor on the SATA SSD fail-stop failures [1, 24, 36, 41, 47]. The key difference between workloads is the I/O pattern. Therefore, we evaluate the impacts of workloads by studying four representative cloud storage services with drastically different access patterns, namely block storage, buffering, object storage, and query.

| G | Age-Wr | Wl. | Slow Drive (%) | Event Freq. | Dur. (min) | Slow-down Ratio |
|------------|---------|--------|----------------|-------------|------------|-----------------|
| II-D-3840 | | | | | | |
| 1 | 3rd-2nd | Block | 0.02 | 0.23 | 9.81 | 1.99 |
| | | Buffer | 39.17 | 1318.51 | 11.85 | 2.28 |
| | | Query | 0.08 | 2.31 | 6.83 | 3.01 |
| 2 | 3rd-3rd | Block | 0.01 | 1.84 | 19.60 | 2.15 |
| | | Buffer | 13.86 | 466.00 | 13.38 | 2.22 |

| | | Buffer | 10.18 | 608.78 | 20.24 | 2.39 |

Table 6: Fail-slow statistics for groups of workloads (§5.3.2). The table presents fail-slow metrics under different workloads with control variables on the drive model, age, and P/E cycle (total bytes written divided by capacity) under 5-min duration requirement. **G**: variable-controlling group; **Age-Wr**: age-write bucket; **Wl.**: workload; “Slow Drive (%)” to “Slow-down Ratio” follow the same metrics in Table 5.

As factors like age and manufacturers could severely influence the fail-slow failures, we thus conduct this study in a finer granularity by setting multiple variable-controlling groups. In Table 6, based on the fail-slow metrics under 5-min duration requirement, we group the drives (G column) by drive model, age, and P/E cycle (total bytes written divided by capacity). We choose two drive models, II-D-3840 (upper half) and III-B-3800 (lower half), as they are from different manufacturers and both popular among different services. Then, we control other variables as Age-Wr (age and P/E cycle). The age is listed by years and the P/E cycle is broken down into 4 intervals (i.e., ≤ 100 , $100\sim 500$, $500\sim 1K$, and $1K\sim 10K$ P/E cycles, respectively). For example, the 3rd-2nd from group 1 means the drives from this group have a deployment time between 2 to 3 years and a usage level between 100 to 500 P/E cycles. For each group, we further list the workload (Wl. column) and the corresponding fail-slow metrics (“Slow Drive (%)” to “Slow-down Ratio” column, same as Table 5).

Here, we make the following observations. First, by comparing the metrics within each group, we can see that the workload can significantly affect all four fail-slow metrics. For instance, in groups 1 and 2, the fail-slow population and event frequency of buffering workload can be thousands of times higher than those in block storage (e.g., 39.17% vs. 0.02% in group 1). Similar disparities in event duration and slowdown ratio can be observed between block and object storage in group 3, or between block storage and buffering in group 5.

Second, the patterns can preserve despite model, age, or

P/E cycle variances. For example, by comparing groups 2 and 5, while the groups are of different models and usage levels, the buffering workload in both groups has a much higher slow drive percentage and event frequency.

To sum up, the above experiments verify the significant influences of workloads on fail-slow failure. Primarily, we discover that fail-slow failure favors the buffering workload the most. In practice, the drives under the buffering workload usually have constantly heavy traffic (e.g., storing intermediate results of big data workload). Recall that we have already excluded SSDs under heavy traffic from consideration. Therefore, a possible explanation is that the heavy traffic may have a long-lasting effect (e.g., leaving data more scattered), making the drive more susceptible to fail-slow failure.

5.3.3 SMART Attributes

Finding 9. SMART attributes only exhibit negligible correlation with fail-slow metrics.

Now, we analyze whether SMART attributes (an essential set of indicators for fail-stop failures) correlate with fail-slow failures. We collect SMART data on the last day of our four-month fail-slow detection period. Further, we divide drives into groups based on drive model, age, P/E cycle, and workload. Within each group, we label drives as either “slow” or “not-slow”. Finally, we apply SRCC [44] to examine the correlation between fail-slow failures and SMART attributes.

Under the 5-min duration requirement, we obtain 40 groups of drives. None of them exhibit a clear correlation with any SMART attributes, such as Critical Warning, P/E Error, and CRC Error. The above results preserve under 15-min, 30-min and 60-min duration requirements. Even if we set drives with multiple fail-slow events as “slow”, the results remain. Hence, we conclude that the root causes and/or the symptoms of fail-slow failures are not (well) captured by the SMART.

Operational advice. In this case, we decide not to integrate SMART attributes to improve the fail-slow detection. Currently, we have been exploring various approaches. The major hurdle is the lack of verified positive samples (i.e., fail-slow drives) due to the lack of a fail-slow oracle. Therefore, based on the performance, we tried classic statistical methods and discovered that basic linear or polynomial regression is not very practical as they require constant adjustment for the varying traffic (even within the same workload). We leave employing machine learning models as a part of our future work once the “three strikes” yields convincing and abundant cases. Also, we encourage manufacturers to reveal drive characteristics (e.g., flash GC timing) to facilitate fail-slow identification.

5.4 Transition to Failures

Finding 10. The transition from fail-slow to fail-stop failures is rarely observed, at least not observed within a short time interval (within 5 months).

Previous case studies indicate that a fail-slow failure may

| | Not-replaced | Replaced | Total |
|----------|--------------------|-----------------|--------------------|
| Not-slow | 98.84% (770965) | 0.57% (4429) | 99.41% (775394) |
| Slow | 0.59% (4574) | <0.01% (10) | 0.59% (4584) |
| Total | 99.43% (775539) | 0.57% (4439) | 100% (779978) |

Table 7: Transition from fail-slow to fail-stop failures (§5.4). The table presents a contingency table of fail-slow and failed (later in time) drives for NVMe SSDs under the 5-min duration requirement.

turn into a fail-stop failure [17]. Therefore, we collect up-to-date failure tickets ever since the beginning date of our detection period. The latest failure tickets are about 5 months older than the last recorded fail-slow event.

Table 7 is a sample contingency table recording the frequency counts of drives based on 2 categories: appearing in the failure tickets (Replaced column) or not (Not-replaced column) and having at least one fail-slow event (Slow row) or not (Not-slow row). The result is rather surprising as only 10 drives exhibit fail-slow failures before fail-stop failures, yielding a relatively small population in both slow (around 0.22%) and replaced (around 0.23%) drives. The mean and median transition time are 73 and 67 days, respectively. A possible reason is that fail-slow seldom or may need a long time to transit to a fail-stop failure. Therefore, we conclude the fail-slow failures are unlikely to transit to fail-stop failures, at least not within a few months.

6 Limitation

Environmental differences. The main methodology of this paper is to draw side-by-side comparisons with previous findings. The environmental differences (e.g., workload and hardware setup) may impact the validity of our findings. Therefore, throughout the study, we use controlled-variable experiments to rule out the biases led by such influences and only make findings when statistical confidence is enough. Plus, many previous studies share great similarities with our setups (i.e., cloud storage systems from [19, 35, 36, 47]) and workloads (e.g., object storage in [19, 36, 47] and database storage in [36, 47]). Hence, our findings are a result of the NVMe SSD characteristics instead of the environmental factors.

Comprehensiveness. Previous studies have covered various aspects of SATA SSD failures. Due to the space limit, we are unable to present all of them. In the paper, we do not discuss the topics due to three reasons: missing data sources (e.g., bus power consumption [35]), statistically unconvincing results (e.g., lithography [34]), and unchanged failure patterns.

Fail-slow detection. Unlike fail-stop failures where the oracle is clear (i.e., the five symptoms in Table 3), fail-slow failures are often difficult to pinpoint and thus rely on empirical thresholds. In the study, we place a rather strict threshold

and drives under heavy traffic are not considered. The average event latency (close to SATA SSD performance), shown in Table 5, confirms the effectiveness of our detection approach. Even though we may underestimate the impacts of fail-slow occurrences due to the demanding standards, we believe our dataset and findings are sufficient to reveal a rather concerning status quo of fail-slow NVMe SSD in the field.

7 Related Work

SATA/SAS SSD failure study. There are several field studies of SSD failures in large datacenters, including NetApp [34], Google [4, 41], Alibaba [19, 47], Facebook [35], and Microsoft [36]. These studies share important insights regarding the trend, impacting factors, and correlation of the SATA/SAS SSD failures in the field. Our study distinguishes from them in two aspects. First, we focus on NVMe SSD, which can have distinctive failure characteristics due to internal (e.g., RAIN) and external (e.g., NVMe interface) changes. Second, apart from fail-stop failures, we also study the fail-slow failures, a pressing issue especially for the NVMe SSD.

Fail-slow failure study. Fail-slow failure (aka. gray failure) has attracted increasing attention from academia and industry [13, 17, 21, 22, 25, 26, 37]. Specifically, Gunawi et al. [17] collect more than 100 hardware fail-slow cases from various datacenters and perform qualitative analysis to understand the distribution and root causes behind the failures. Moreover, Hao et al. [21] reveal the distribution of tail latency in large-scale SSD/HDD-based RAID systems. Our work is different from the above as we focus on NVMe SSDs inside the general-purpose cloud storage system and perform large-scale quantitative analysis based on the monitoring data.

8 Conclusion

We perform a large-scale failure study of NVMe SSDs in the field. We have identified major changes of NVMe SSD fail-stop failure patterns including failures, robustness under WAF and the temporal correlation. Also, we investigate the fail-slow failures and the impact factors at scale. Altogether, we obtain 10 findings and open-source our dataset.

Acknowledgements

A Artifact Appendix

Abstract

The artifact consists of the first large-scale public dataset on real-world operational data of NVMe SSD. With this dataset, we have identified a series of major reliability changes in NVMe SSD. The community could leverage our dataset and findings to understand the major reliability changes in NVMe SSD, and design effective reliability solutions (e.g., detecting and predicting failures) in production environments.

Scope

Most major findings in the main text (i.e., Findings 1-8 and 10) could be validated by exploring the dataset. Moreover, practitioners could make use of this dataset to investigate the *fail-stop* and *fail-slow* failure characteristics of NVMe SSD. For example, the dataset could be used to design fail-slow detection algorithms or to predict fail-stop or fail-slow failure occurrences in large storage systems.

Contents

The dataset primarily covers:

- **SMART logs and failure tickets** of around 700K NVMe SSDs of 11 drive families from three vendors during a one-year span. Practitioners could make use of them to investigate the *fail-stop* failure characteristics of NVMe SSD.
- **Performance logs** (i.e., device-level write latency time series) of around 97K NVMe SSDs and 141K SATA HDDs. Practitioners could make use of them to investigate the *fail-slow* failure characteristics of NVMe SSD, and compare them with those of SATA HDD.

Hosting

The open-source dataset is hosted by Tianchi of Alibaba Cloud at <https://tianchi.aliyun.com/dataset/dataDetail?dataId=128972> with detailed instructions. Please refer to the above link for more information. We commit to ensuring the availability of this dataset.

CacheSack: Admission Optimization for Google Datacenter Flash Caches

Tzu-Wei Yang, Seth Pollen, Mustafa Uysal, Arif Merchant, and Homer Wolfmeister

Google Inc.

{twyang, pollen, uysal, aamerchant, wolfmeister}@google.com

Abstract

This paper describes the algorithm, implementation, and deployment experience of CacheSack, the admission algorithm for Google datacenter flash caches. CacheSack minimizes the dominant costs of Google’s datacenter flash caches: disk IO and flash footprint. CacheSack partitions cache traffic into disjoint categories, analyzes the observed cache benefit of each subset, and formulates a knapsack problem to assign the optimal admission policy to each subset. Prior to this work, Google datacenter flash cache admission policies were optimized manually, with most caches using the Lazy Adaptive Replacement Cache (LARC) algorithm. Production experiments showed that CacheSack significantly outperforms the prior static admission policies for a 6.5% improvement of the total operational cost, as well as significant improvements in disk reads and flash wearout.

1 Introduction

Colossus Flash Cache (Figure 1) is the general-purpose flash cache service for Colossus [20], the successor to the Google File System [19]. Disk reads are expensive and are a major cost in datacenters: while disks are growing in storage capacity, the IO capacity (the ability to offer disk accesses per second, mainly disk reads) is not growing proportionally. As a result, to provision the IO requirements, we need to deploy a lot of hard disks that are not for storage but for the target IO capacity, which is costly.

Colossus Flash Cache provides a cost-effective way to improve IO capacity while costing a fraction of an equivalent RAM cache or deploying more hard disks. The primary design goal of Colossus Flash Cache is to reduce the amount of hard disk reads, in order to reduce disk IO requirements and costs.¹ Colossus Flash Cache serves the read traffic of many widely-used Google services including Colossus and database

¹While reducing read latency is also a desirable goal, it is not a design goal for Colossus Flash Cache, and beyond the scope of this paper.

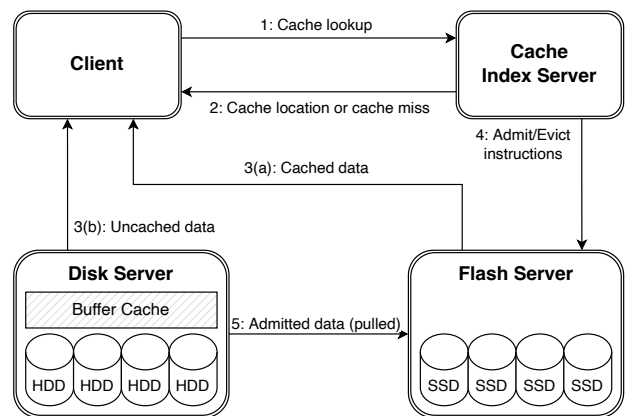

Figure 1: Colossus Flash Cache system.

systems such as BigQuery [37], BigTable [11], F1 [34], and Spanner [13].

CacheSack is the cache admission algorithm used by Colossus Flash Cache, intended to minimize the total cost of ownership (TCO). Compared to a RAM cache, a flash cache usually provides a much larger cache-to-storage capacity, and so a simple algorithm such as LRU may achieve a good cache hit-ratio. An idealized LRU is difficult to implement in a flash cache; we address this issue in Section 4. However, flash memory has limited write endurance, so may cause premature flash wearout and increase TCO. Write amplification and flash wearout, along with caching in Colossus disk servers, form a special challenge for designing a cache algorithm for Colossus Flash Cache.

2 Our contributions

CacheSack is the cache admission algorithm for Colossus Flash Cache, the successor to LARC (Lazy Adaptive Replacement Cache). CacheSack dynamically analyzes the cacheability of a workload and the given cache size, making the admis-

sion decision for the workload. CacheSack was deployed in Colossus Flash Cache in May 2021 and is now Colossus Flash Cache’s default cache admission algorithm. Our contributions are summarized as follows:

- CacheSack partitions traffic into multiple categories, estimates the disk reads and cost of write of each category, and formulates a knapsack problem that finds the optimal admission policy per category to minimize the overall cost, including disk reads and bytes written to flash.
- CacheSack effectively reduces the total cost of ownership (TCO) of Colossus Flash Cache. Compared to LARC, it results in 6% lower disk reads, reduces bytes written to flash by 26%, and improves TCO by 6.5% (one week average).
- CacheSack runs in real time, using a fraction of the resources of a cache index server.
- CacheSack is fully decentralized (as is Colossus Flash Cache). It requires only the information received by a single cache index server, and the failure of a single cache index server does not impact others.
- CacheSack supports major Google database systems and requires zero configuration if using these systems. For other applications, users only need to provide category annotations (Section 5.1).

3 Background

3.1 Write amplification

Non-sequential writes to a flash drive can cause serious write amplification [29, 42], a phenomenon where one logical write causes multiple physical writes. A flash byte has to be erased before it can be rewritten. A flash block is a continuous region of bytes in a flash drive and is the smallest unit that can be erased. As a result, a flash drive needs to move the live bytes in a flash block somewhere else before this flash block can be erased, which is called write amplification. Extra writes caused by write amplification reduce the IO performance and the lifetime of a flash drive; both greatly increase the cost of operating a flash cache.

Sequential cache evictions (like FIFO) result in large sequential areas that can be easily erased and reused later when admitting new data. By contrast, non-sequential evictions (such as those caused by LRU) result in a fragmented cache space and the flash drive has to move the interspersed live bytes somewhere else before erasing a block.

As a result, most existing eviction algorithms for RAM caches cannot be directly applied to flash caches, and write amplification is one of the most important factors to consider when designing a flash cache algorithm. Both Google [1] and Facebook [18] use FIFO-based evictions or other special purpose algorithms [36, 44] for production flash caches because of write amplification. Colossus Flash Cache reduces write amplification brought by non-sequential evictions by using

Figure 2: Fraction of bytes accessed a given number of times from disk plus flash over a week (right truncated at 100 accesses).

approximate LRU (Section 4).

3.2 Write endurance

Flash has limited write endurance, and thus admitting all data into Colossus Flash Cache upon write or even upon the first read would wear out the flash too soon, significantly increasing TCO. To mitigate this issue, Colossus Flash Cache previously used Lazy Adaptive Replacement Cache (LARC) [21] to exclude data that are accessed only once by inserting data at the second access. Figure 2 shows that more than 60% of the traffic of Colossus Flash Cache is accessed only once, and so LARC can greatly reduce bytes written to flash and avoid cache pollution.

However, excessive flash writes are still possible with LARC, and as a workaround, Colossus Flash Cache used a write rate limiter to avoid an excessively high write rate. This is, however, a blunt approach, since it does not accurately factor in the impact on overall cost, and treats all workloads similarly. It may be preferable to allow some highly cacheable workloads to burst writes at the expense of other less cacheable workloads rather than throttling all write rates. CacheSack uses a more flexible and accurate approach by optimizing the total costs, including the write costs and the cost of disk reads.

3.3 Capturing second-access hits

LARC leverages the fact that a large fraction of data is accessed only once. Inserting data into cache only upon the second access avoids flash writes for data accessed once, reducing flash wear. However, the cost is that all second accesses are cache misses. Figure 2 shows that of the data accessed more than once in our workloads, 39% is accessed exactly twice, and these second accesses are cache misses under LARC. This has a significant performance impact, as was also observed in Facebook’s cache for social network photos [36]. Our workaround for this when using LARC was to monitor the performance loss, and to manually turn off LARC (i.e., admit all data on the first miss) for workloads that suffered a significant performance penalty. However, the

Figure 3: Miss ratios for 10 workloads at the disk server buffer cache if there is no Colossus Flash Cache (simulated).

manual maintenance to identify and set up special cases became more and more labor-intensive with the rapid adoption of Colossus Flash Cache in production. In our redesign, it was a requirement that the cache admission algorithm should be automatic and not require manual adjustments.

3.4 Colossus buffer cache

In addition to Colossus Flash Cache, Colossus maintains a RAM *buffer cache* in the lower level disk servers that buffers recent reads and writes as well as data prefetched from the disk. A cache miss in Colossus Flash Cache does not cause a disk read if the access hits in the buffer cache. Many Colossus workloads use the buffer cache extensively to improve IO performance.

In many cases, the cache hit ratio of Colossus Flash Cache is only weakly correlated with the actual disk read reduction, especially for workloads that are highly optimized for the buffer cache. Figure 3 shows simulated miss ratios of the disk server buffer caches with no Colossus Flash Cache for ten selected workloads, and they range from below 20% to over 80%. These miss ratios represent the upper bound on how far Colossus Flash Cache can improve the disk read rates. For workloads with low buffer cache miss ratios, hits in Colossus Flash Cache may simply replace buffer cache hits without improving the disk read rates. As a result, flash cache hit ratios are not a good metric to measure the efficacy of Colossus Flash Cache. In fact, our production results (Section 7.1) show that an admission policy can sometimes provide a higher hit ratio in Colossus Flash Cache but cause worse disk read rates.

3.5 Online and realtime requirements

Colossus Flash Cache is a fully decentralized system, so its cache algorithm can only use the resources of individual cache index servers, and heavyweight algorithms, such as machine learning (ML) models, may not be feasible. The binary of Colossus Flash Cache is updated on a weekly basis, while workloads change much more rapidly, so it is difficult for an offline-trained static model updated with the binary to adapt

to workload changes. Therefore, we decided to use an online-trained model.

4 Overview of Colossus Flash Cache

Colossus Flash Cache consists of independent cache index servers. A cache index server does not directly hold cached data, but keeps an in-memory lookup table, called the index, that tracks the locations of cached data stored in the flash drives that reside on independent storage servers.

When a Colossus Flash Cache client requests to access data stored in Colossus, the client first sends an RPC to a Colossus Flash Cache cache index server (see Figure 1) to determine if the requested data are already cached on a flash server (a flash hit). If so, the cache index server sends back sufficient information for the client to access the flash copy of the data directly from the flash server. For a flash cache miss, the client contacts the disk server to read the data, while the cache index server independently decides whether to admit the data into the flash cache. If the cache index server decides to admit the data into flash, it instructs the flash server to pull the data from the disk server directly. The extra latency of communicating with the cache index servers is negligible compared to typical remote disk read latencies, and the latencies between remote flash reads and remote disk reads are in different orders of magnitude, so Colossus Flash Cache typically reduces overall latency, although this is not an explicit service goal. The goal is reducing TCO by avoiding expensive disk reads.

The *buffer cache* of a disk server also caches recently accessed data and prefetches a small amount of data into memory for a few seconds, so that reading recently-accessed data from an disk server does not necessarily cost extra disk reads. Colossus users are encouraged to design their workloads to improve IO performance by utilizing this buffer cache.

Colossus Flash Cache uses an *approximate* LRU eviction strategy to manage evictions. An idealized LRU cache would always evict the least recently used block from the cache when the cache is full. However, idealized LRU evictions cause non-sequential writes to flash, resulting in write amplification [29, 42]. To mitigate the issue of write amplification, Colossus Flash Cache uses evictions similar to Second Chance [30] to approximate LRU evictions: each Colossus Flash Cache cache index server manages a FIFO queue of many fixed-sized Colossus files (typically 1 GiB), each of which contains cache blocks. When evicting the file from the tail of the queue, we reinsert 28% of the most-recently-used blocks into the file at the head of queue. The percentage of the reinserted blocks is a tradeoff between the amount of hot blocks recycled, which improves the cache hit ratio, and the rate of reinsertion into flash, which increases write amplification. The current value (28%) is selected experimentally to strike a good balance between cache performance and write amplification. This way, the write amplification factor is effectively 1.28. A comparison of the performance of Second

Chance [30] indicates that the performance is quite close to that of LRU. Therefore, for ease of modeling, we approximate Colossus Flash Cache as an LRU cache.

Each Colossus Flash Cache server maintains a *ghost cache* [21], an in-memory lookup table that maps the key of data to the data’s last access time, regardless of whether they are actually cached on flash. This is a key component of CacheSack, which relies on inter-arrival times to quickly build all the estimates described in Section 5.

Each cache index server represents a fraction of the key space, and one server’s failure does not impact other cache index servers. To maintain the same reliability, CacheSack is also designed in the same decentralized manner: each cache index server runs its own CacheSack model, using only the information received by the cache index server, and its admission decisions do not affect other cache index servers.

5 CacheSack

5.1 Traffic partitioning

CacheSack partitions potential cache blocks into many *categories*, and assigns an admission policy to each category.

The majority of Colossus Flash Cache traffic comes from Google’s database systems like BigTable and Spanner where categories can be well-defined. For database traffic, CacheSack defines a category as the combination of the table name, locality group [11, 13], and type for BigTable and Spanner, and a similar combination for other databases. Since Colossus Flash Cache is also available for other Colossus users, those users can define their own categories by annotating their data. If a user does not provide a category annotation, CacheSack will use the user name contained in the Colossus file path.

CacheSack then selects the right policy based on the pattern that category exhibits. Later, we will explain how we formulate CacheSack as a knapsack-like problem: given the cache capacity, how CacheSack chooses the items (categories) to minimize the overall cost.

5.2 Admission policies

We consider four admission policies that can be assigned to each category:

- **AdmitOnWrite**: Inserts a cache block at a write access or on any read cache miss.
- **AdmitOnMiss**: Inserts a cache block on any read cache miss, but does not insert a block at a write access. This is the conventional admission policy used in most of the cache literature.
- **AdmitOnSecondMiss (LARC)**: Equivalent to Lazy Adaptive Replacement Cache (LARC); Inserts a block only after the second read access (miss), and only if the last access time is not older than the oldest last access time of the blocks in the cache, to reduce the insertion

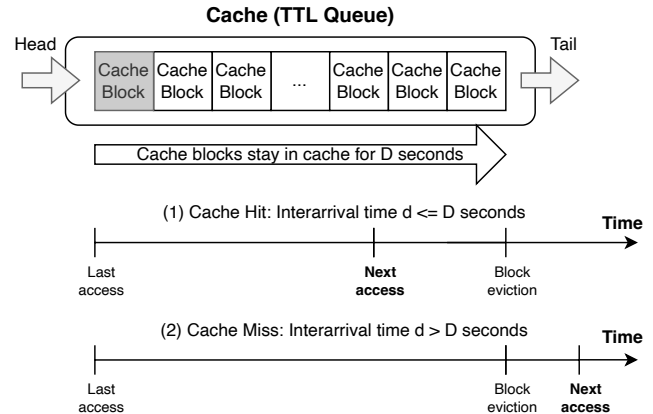

Figure 4: LRU evictions are approximated by TTL evictions with the modeled retention time D while the TTL counter of a cache block is reset whenever the cache block is accessed. If the access interarrival time d is less than or equal to D , this access is a cache hit and we move the cache block to the head of the queue (the TTL counter is reset). If the access interarrival time d is greater than D , this access is a cache miss and we insert the cache block to the head of the queue (the TTL counter is also reset).

rate of cold blocks. LARC is scan resistant: any scanned data (accessed exactly once) will not be admitted.

- **NeverAdmit**: Never inserts blocks.

We can sort these policies by aggressiveness: $\text{NeverAdmit} < \text{AdmitOnSecondMiss} < \text{AdmitOnMiss} < \text{AdmitOnWrite}$.

5.3 Fast approximation to an LRU model

To determine the best policy for the cache, the most intuitive way is to simulate all possible policy-category combinations, which is a combinatorial knapsack problem (NP-Hard). Because CacheSack currently allows up to 5000 categories (Section 6.1) and uses 4 policies, there are up to 4^{5000} combinations and the knapsack problem can not be done even with downsampled traces. Instead, we use a fast approximation for modeling an LRU cache, by introducing the *modeled cache retention time*. The cache retention time is the maximum duration that a block stays in the LRU cache without any intervening accesses to it. In practice, the cache retention time varies slowly over time. Here we assume the *modeled cache retention time* is a constant D and this assumption will make all our estimates just approximations.

We use **AdmitOnMiss** as an example. For a given block, when a read access arrives, we can compute d , the time since last access (which is ∞ if the current access is the first read). We can classify the inter-arrival times by using D (Figure 4):

- $d \leq D$: An access arrives before the block leaves the cache, and therefore the access generates a cache hit and moves the block to the head of the queue.

- $d > D$: An access arrives after the block leaves the cache, and therefore it is a cache miss, which causes a write to the cache.

In other words, we approximate the LRU cache by a cache that has the TTL value D and resets the TTL counter of a block when receiving an access to the block. The theoretical aspect of the TTL approximation was also studied in literature. Fagin [17] showed the TTL approximation is asymptotically exact for independent and identically distributed requests, and [23] proved that given the assumption that data accesses are stationary and ergodic, the TTL approximation will converge to an LRU cache as the cache size goes to infinity. The accuracy of the TTL approximation in production is analyzed in Section 7.1.

A cache miss in Colossus Flash Cache will cause a disk read if it is also a miss in the Colossus buffer cache. Each cache index server maintains a *buffer cache simulator*, and when $d > D$, we run the simulator and see whether it is a miss.

This way, when a new access arrives, we are able to update the disk reads, cache usage, and bytes written to flash cache caused by admitting the block using `AdmitOnMiss`. We can also compute the same quantities for other policies: `AdmitOnSecondMiss`, `AdmitOnWrite`, and `NeverAdmit`. The detailed estimation is described in Appendix A.2.

A nice property of this approximation is that the estimates for a block are not affected by other blocks or policies, as long as the modeled cache retention time is given. Therefore, the disk reads, cache usage, and written bytes caused by admitting a category are just the sums of the corresponding block-level quantities.

5.4 Knapsack problem

Once we have the estimates for disk reads, cache usage, and bytes written to flash cache for each policy-category pair, we have a knapsack problem: find the optimal policy per category to minimize the overall cost (disk reads and written bytes) while fitting within the cache. We omit the definitions of the relative cost of disk reads, bytes written to flash, and flash storage, because they are confidential.

We further allow *fractional* policies: CacheSack can apply a policy to a fraction of a category. For example, CacheSack may decide it is optimal to apply `AdmitOnMiss`, `AdmitOnSecondMiss`, `AdmitOnWrite`, and `NeverAdmit` to 30%, 20%, 10%, and 40% of blocks in a category, respectively. Then the problem becomes a *fractional* knapsack problem [14] that finds the optimal policy fractions per category to minimize the overall cost. The advantage of considering a fractional knapsack is that it can be solved efficiently by a greedy algorithm, as opposed to a combinatorial knapsack that is NP-Hard. Our problem is slightly different from the original fractional knapsack in [14] because we need to decide four fractions per category instead of two. Appendix A.4

explains the details of how we solve our problem by a greedy algorithm after applying Andrew’s monotone chain convex hull algorithm [2]. We note that if an LRU cache is perfectly modeled by the TTL approximation, the resulting cache retention time of the LRU cache is exactly D after applying the optimal policy fractions per category.

5.5 Optimization over modeled cache retention times

The knapsack problem in Section 5.4 is to find the optimal policy fractions for a *given* modeled cache retention time D , which can not be known in advance. Thus, we need to solve the same knapsack problem for *all* possible D . To do this in production, we can have a set of predefined modeled cache retention times: $0 < D_1 < D_2 < \dots < D_m = \mathbf{D}$ where \mathbf{D} is a suitable upper bound, and solve m different knapsack problems. Thanks to the greedy algorithm, we can still solve many knapsack problems (currently 127, Section 6.2) quickly.

6 CacheSack in production

CacheSack is now deployed in production as the default cache admission algorithm for Colossus Flash Cache. This section explains the engineering efforts needed to do so.

6.1 Category assignment

The number of categories encountered in production can not be known in advance, so we balance the need for accuracy and space by hashing a category to one of 5000 buckets. Categories assigned to the same bucket are treated as combined in the optimization. The number of hash buckets is a trade-off between memory usage and hash collisions. The typical number of categories per server is less than 100 and our experiments showed that with 5000 buckets, 95% of the clients see a hash collision rate lower than 1% and the worst collision rate is less than 5%. Further, cache collisions are not persistent, since each cache index server uses a different hash key and changes it periodically to break possible spatial and temporal correlations.

A bucket without sufficient training data might not provide meaningful metrics. If a bucket contributes to less than 0.1% of total lookups, it will be aggregated to a single *catch-all* bucket before solving the knapsack problem.

6.2 Modeled cache retention times

Currently, CacheSack uses 127 predefined cache retention times: 15 minutes, 1.06×15 minutes, $1.06^2 \times 15$ minutes, ..., $1.06^{126} \times 15$ minutes ≈ 16 days; the 128th value is reserved for positive infinity.

These retention times are decided in the following way. We first determine the working range. A retention time less

than 15 minutes means we evict and insert cache blocks in an extremely aggressive way, which would cause serious flash wearout. By policy, any cache block is forced to leave the cache if it stays more than 15 days. Hence we set the modeled working range of retention times as 15 minutes to 15 days. We then decide the number of retention times to model. We tried 127 (6% geometric increase) and 255 (3% geometric increase) retention times, and our experiments showed that 127 retention times gave similar results while reducing RAM usage by half.

6.3 Ghost cache

Since LARC was Colossus Flash Cache's previous admission control, a *ghost cache* was implemented in cache index servers. It is an in-memory lookup table that maps a data's key to the data's last read access time, and LARC uses the information to determine whether to admit the data on miss. CacheSack uses the same ghost cache to obtain inter-arrival times. In addition, to build the metric estimate for `AdmitOnWrite`, we expanded the ghost cache so that we know whether the last access is a write access. To build the metric estimate for `AdmitOnSecondMiss`, we use the ghost cache to record the most two recent access times.

Because the ghost cache is the ground truth for CacheSack, the ghost cache must contain sufficient history. The optimal solution of CacheSack will not be affected as long as the ghost cache TTL, the time since the oldest last access time of the blocks in the ghost cache, is greater than the optimal modeled cache retention time. As a rule of thumb, we provision the size of the ghost cache so that its TTL is at least twice the solved optimal modeled retention time (typically about four hours).

6.4 Buffer cache simulators

A cache miss in Colossus Flash Cache causes a disk read only if it is also a miss in the buffer cache. CacheSack simulates the buffer cache to determine whether the current miss in Colossus Flash Cache is also likely a miss in the buffer cache. In fact, we need *many* simulators: one for each pair of policy-retention time so there are 382 simulators ($3 \times 127 + 1$, the retention time does not affect `NeverAdmit`). Running the simulators is the most computationally intensive component in the CacheSack model. Fortunately, the buffer cache simulator is simple enough and only requires the access history in the past few seconds so it only moderately increases CPU load on the low-QPS servers (5% CPU usage).

6.5 Model training

We use a simple scheme to train the CacheSack model: the model is reset every 5 minutes and is trained based on the

lookups in this 5-minute period. We note that a lookup contains the access times of the most recent two accesses and therefore the lookups in a 5-minute period may contain the information of many hours.

The selection of the training duration is a trade-off. Using a larger training duration means the model can be improved by more training data and longer time horizon, while the model can react more quickly to changes in the workload with a shorter duration. We tested several training durations and found that 5-minute one gave most disk read reduction, although we did not find significant differences among all candidates.

6.6 Lessons learned

Automatic cache optimization incentivized user adoption

In deciding whether to use Colossus Flash Cache, users weigh both the likely TCO improvement and the engineering effort required to configure and maintain it. In the past, users had to manually choose the admission policy (using `AdmitOnMiss` or `AdmitOnSecondMiss`) based on knowledge of their workload or by running A/B experiments with the assistance of the Colossus Flash Cache team. For heavy users like Spanner, Colossus Flash Cache had to provide heuristic, hand-tuned admission policies to improve cache performance. Such human tuning and maintenance usually requires effort from both the users and the Colossus Flash Cache team, which can discourage the adoption of Colossus Flash Cache if the expected hardware resource saving does not justify the extra engineering cost.

We found that CacheSack greatly incentivized users to adopt Colossus Flash Cache. The automatic cache provisioning brought by CacheSack requires almost no configuration and maintenance so that it can be set and forgotten. We found that new users were more willing to use Colossus Flash Cache once they knew it would automatically adjust the cache policy based on their workloads.

Some of Colossus Flash Cache's existing users have independently verified that CacheSack applied appropriate admission policies to their workloads, based on the knowledge of their workloads and reporting provided by Colossus Flash Cache. One user experimentally overrode CacheSack with manually optimized policies and found that CacheSack worked as well as manual policy tuning. After CacheSack became the default admission policy in Colossus Flash Cache, we were able to retire the hand-tuned optimization for Spanner, and our existing users did not need to manually adjust the policy anymore.

Experiment infrastructure accelerated feature development

The development of CacheSack was significantly benefited by the experiment infrastructure of Colossus Flash Cache.

The experiment infrastructure allows developers to test new features by using 10% of the cache index servers, and because cache index servers are independent and isolated, any experiment can only cause minor service degradation in the worst case. Before the full deployment, we ran CacheSack as an experiment for a few months and most of the issues were identified and corrected during the experimental phase. In fact, there was no binary rollback caused by CacheSack since the full deployment.

In addition, because each server represents a fraction of the key space, which is permuted randomly, each server is statistically indistinguishable. We can have simultaneous comparisons between CacheSack and the control group to see whether CacheSack works as expected and identify any issues. The experiment infrastructure is extensively used by the developers of Colossus Flash Cache for new features, and the impact of a new feature can be accurately measured before the full deployment.

Model introspectability and maintainability played important roles

We found that the model introspectability played an important role for the adoption of the new cache algorithm. Because any cache algorithm of Colossus Flash Cache will be operated and maintained by developers and site reliability engineers (SREs) after the initial deployment, one requirement of deploying a new cache algorithm is that the model behavior can be fully understood and monitored by the developers and SREs. CacheSack satisfies this requirement as it only assumes that the TTL approximation (Section 5.3) is sufficiently close to the eviction of Colossus Flash Cache, and all model behaviors can be derived from this assumption. Another advantage of a highly introspectable model is that the developers (besides the original designers) of Colossus Flash Cache can easily ensure thorough test coverage, validate software releases, add extend the original functionality of CacheSack without assistance from the original designers. After the deployment of the original CacheSack, it became the foundation of further optimizations for Colossus Flash Cache.

It is also worth mentioning that CacheSack is simple enough to be implemented by limited extensions to the original codebase of Colossus Flash Cache. In particular, the optimization was implemented as a simple greedy algorithm instead of using a generic linear program solver library. This did cost extra time for development, but we decided to do so because it allowed us to minimize the computational overhead and increase system reliability by reducing external dependencies. More importantly, anyone familiar with the ecosystem of Colossus Flash Cache can easily maintain CacheSack or develop new features based on it. The implementation of CacheSack can evolve continuously with Colossus Flash Cache, reducing maintenance burden. Since the completion of the initial deployment, both maintenance and new feature devel-

Figure 5: CacheSack disk read rate prediction errors relative to the actual value in production (CDF).

opments have been completely handled by Colossus Flash Cache developers and SREs without the need for involvement from the original designers.

7 Evaluation

7.1 Production evaluation

Model accuracy

There are two LRU approximations in Colossus Flash Cache: Colossus Flash Cache uses Second-Chance-like approach to approximate LRU evictions (Section 4), and CacheSack models an LRU cache as a TTL approximation (Section 5.3). Therefore, it is important to verify that the CacheSack model is a good enough approximation to the actual Colossus Flash Cache. We examined the accuracy of CacheSack in the following way. For each client, the solution to the knapsack problem in Section 5.4 gives the predicted disk reads when using the optimal admission policies. Then Colossus Flash Cache applies the optimal policies in production so we compared the predicted disk reads with the actual disk reads. Figure 5 shows the prediction errors of CacheSack relative to the actual values obtained from the disk servers; 51% of the relative errors are within 10% and 82% of the relative errors are within 20%.

Policy distribution

Figure 6 shows the policy distributions suggested by CacheSack in the selected datacenters of various workloads. We can see that each datacenter has a different workload pattern and CacheSack adaptively decides suitable admission policies based on workloads and cache sizes. Although it would be possible for manual selection of static policies to match each datacenter workload, CacheSack is able to reduce the human toil, response delay, and operational complexity required to maintain these assignments.

Figure 6: Policy distribution suggested by CacheSack in selected datacenters, demonstrating a variety of workload responses.

Figure 10: Hit ratios in Colossus Flash Cache of different admission policies in production.

Production experiments

By using the experiment infrastructure of Colossus Flash Cache, we can compare the performance of different cache algorithms in production. Because each cache index server represents a fraction of the key space, the pattern of workload each cache index server receives is statistically indistinguishable. We let 10% of the cache index servers run static AdmitOnMiss and another 10% of the cache index servers run AdmitOnSecondMiss so that we can compare CacheSack, static AdmitOnMiss and static AdmitOnSecondMiss simultaneously in production.

From Figure 7 and 8 we see that compared to AdmitOnSecondMiss, CacheSack results in fewer disk reads (6% of one week average) and reduces 26% (one week average) written bytes to flash, and Figure 9 shows that CacheSack effectively reduces the total operating cost in production: the cost of disk reads, flash cache writes and flash storage of CacheSack is 93% of AdmitOnSecondMiss and is 78% of AdmitOnMiss (one week average).

Figure 10 shows that CacheSack has a higher hit ratio than AdmitOnSecondMiss but lower than AdmitOnMiss. Nevertheless, AdmitOnMiss is not the best choice. Figure 7 shows that AdmitOnMiss has the worst disk read reduction even though it has the highest hit ratio. Because of the lower-level buffer cache, a higher hit ratio in the flash cache does not necessarily imply fewer disk reads: many major Colossus users optimize their workloads by accessing the same data many times within the first few seconds so that only the first access causes an actual disk read. In this case, AdmitOnMiss generates many hits that do not reduce disk reads at all. AdmitOnSecondMiss resolves this issue by avoiding a cache insertion if the most recent access time is too recent to expect that the data has left the buffer cache.

7.2 Evaluation by simulations

In addition to production experiments, we also used the *Colossus Flash Cache simulator* to test the performance of CacheSack in a variety of configurations and contexts, such as

Figure 11: Hit ratios in Colossus Flash Cache of different admission policies in simulation. Above: Original hit ratios. Below: Values relative to AdmitOnSecondMiss.

cache size and optimization iteration period. The Colossus Flash Cache simulator is used for multiple purposes including performance-regression testing by Colossus Flash Cache developers and for datacenter resource planning by Colossus Flash Cache clients. The Colossus Flash Cache simulator uses the same production code as Colossus Flash Cache and we use production traces as the input of the simulator.

We first compare the performance of CacheSack, to the static admission policies AdmitOnMiss, AdmitOnSecondMiss and AdmitOnWrite for various cache sizes. We use here a two-day trace from one large (order of million QPS) production cache as a representative. This trace reflects a uniform sample of the data accesses from a large collection of internal production workloads.

Impact of cache size on performance

When the cache size is small, AdmitOnSecondMiss has a better performance than AdmitOnMiss or AdmitOnWrite because single-use keys are excluded. On the other hand, AdmitOnMiss and AdmitOnWrite will outperform AdmitOnSecondMiss for a large cache because the cache benefit of second accesses is gained.

CacheSack learns to use a more conservative policy for a small cache and a more aggressive policy for a large cache. Figure 11 and Figure 12 show that CacheSack can provide a good performance for the entire range of flash cache sizes.

It is also interesting to see the amount of written bytes

Figure 12: Disk reads of different admission policies in simulation. Above: Constant scaling by dividing the values by the average value for AdmitOnSecondMiss. Below: Values relative to AdmitOnSecondMiss.

caused by different admission policies in Figure 14. For AdmitOnMiss, AdmitOnWrite and AdmitOnSecondMiss with excessively small cache, blocks are frequently evicted from and reinserted into the cache, resulting in a very large amount of written bytes, especially for AdmitOnMiss and AdmitOnWrite. CacheSack, on the other hand, takes into account the cost of written bytes, and therefore only admits the most valuable part of the workload into the cache.

We can also view the total cost (a confidential function of disk reads, flash storage, and written bytes) as a function of cache size. When the cache size is small, disk reads and writes to flash are the largest contributions to cost, while flash storage is the largest cost component for larger cache sizes. Therefore, the total cost is a U-shape curve and we are able to find the optimal cache size that minimizes the total cost. Figure 13 shows that CacheSack gives the lowest total cost for all cache sizes. CacheSack avoids the trade-off and provides robust good behavior over the range of cash sizes.

Optimization frequency

We evaluated the system performance on the choice of different optimization frequencies. Here we test different lengths of training duration from one minute to eight hours, which span a majority of the observed time variation of workloads. Figure 15 shows that the training duration does not significantly impact the performance and all the cost metrics are

Figure 13: Total cost (a function of disk reads, flash storage and written bytes) of different admission policies in simulation. Above: Constant scaling by dividing the values by the average value for AdmitOnSecondMiss. Below: Values relative to AdmitOnSecondMiss.

similar. Because this method is insensitive to this parameter, customized or automated tuning was deemed unneeded, and the entire deployment currently uses a single value.

8 Related work

Production flash cache algorithms

Both Google [1] and Facebook [18] were using FIFO-based evictions in their production flash caches to trade cache performance for managed write amplification. RIPQ [36] is a non-FIFO, advanced flash cache algorithm that brings higher hit ratios while write amplification is well-control. Flashfield [16] further improves RIPQ’s write amplification by using DRAM as a buffer, and only writes flash-worthy objects into flash, predicted by a lightweight support vector machine classifier. CacheLib [7] resolved Flashfield’s issue that the TTLs of objects in the DRAM buffer are too short to be effective. CacheLib uses Bloom filters to count the number of accesses per object in the past six hours (similar to TinyLFU [15]), to predict the number of accesses in the future, and use FIFO for eviction. Kangaroo [26] further improves CacheLib’s performance for tiny objects. DSS [28] uses predefined rules to classify I/O requests into different priorities, and applies heuristic admission and eviction policies to different priorities. DSS has been implemented in Intel’s Cache Acceleration

Software. Amazon’s AQUA [3], which is conceptually similar to CacheSack, analyzes workload patterns to place data into the appropriate tier.

CacheSack’s high-level idea is similar to Flashfield and CacheLib: keep the eviction simple to control write amplification, and use a more sophisticated admission to improve cache performance and flash write endurance. For evictions, Flashfield uses the CLOCK [12] approach and CacheSack uses Second Chance [30] to achieve LRU-style evictions. On the admission side, instead of using DRAM as a buffer, CacheSack has no in-memory buffer and expands the metadata table (ghost cache) for a more complete history; the median of the ghost cache TTL is 20 hours, which is several times longer than the information used by Flashfield and CacheLib. With a more complete history, CacheSack is able to build a more sophisticated model for admission. CacheSack also considers the two major costs of operating flash caches, disk reads and flash wearout, as a whole, and minimizes the overall operation cost.

CacheSack also utilizes the advantage that the categories are well-defined in the database systems served by Colossus Flash Cache. Classifying unstructured data is usually a difficult problem in machine learning. For Google’s database systems, the classification is naturally given, and the categories often hint their cacheability.

Admission algorithms

LARC [21] was previously used by Colossus Flash Cache as the default admission policy. LARC is designed for flash caches, and reduces write rate by inserting an object into the cache only when it is read a second time, based on the observation that most objects are read only once. Thus, inserting only the objects that are read a second time into the cache significantly reduces the write rate and the cache pollution. This strategy is particularly useful when a significant portion of the traffic is accessed only once, for example, Tencent’s photo traffic [41], and AliCloud [24]. However, LARC loses all the first cache hits and becomes undesirable for long-tail accesses like Facebook’s cache for social network photos. In the past, Colossus Flash Cache disabled LARC for workloads in which LARC underperformed. Selective admissions like TinyLFU [15] (non-window version) and HEC [42] that sacrifice the first few hits to determine the cacheability of data likely have the same issue.

TinyLFU [15] works by comparing the expected hit ratio of a newly accessed object against that of the object that would be evicted next from the cache, inserting the new object if its likely hit ratio is higher. Any eviction policy can be used to select the eviction victim (LRU is typical). TinyLFU predicts hit ratios for the objects using approximate counting (Bloom filters) of access frequency. TinyLFU also needs some extra structures to work properly: *Doorkeeper* is used to filter one-accessed blocks (the same use of LARC’s ghost cache), and a

DRAM buffer cache in front of TinyLFU (W-TinyLFU). All these structures require extra parameter tuning, which does not best fit the needs of Colossus Flash Cache as a general-purpose cache. mARC [32] uses ARC [27] as the eviction policy and dynamically determines whether to admit data on the first miss (naive ARC) or second miss (LARC). UBC [31] proposes a low-overhead mechanism to partition shared on-chip cache.

Eviction algorithms

There are also extensive studies on advanced eviction algorithms. Beckmann and Sanchez’s method [5] evicts a block based on the block’s economic value added. Instead of LRU or LFU that require specific data structures, Hyperbolic Caching [9] evicts a block based on a time-decay (hyperbolic) value function and uses a sampling technique to resolve the issue of the data structure requirement. Similarly, LHD [4] evicts the block of the lowest hit density, the number of hits per cache byte-second, and also applies a sampling technique to overcome the data structure issue. Hawkeye [22] assumes that the recent history can predict the near future and hence one can train a predictor learned from Belady’s OPT [6] running on the recent traces. [40] considers an ensemble of candidates, which can be a set of existing algorithms, or the same algorithm with different parameters, runs scaled-down simulations on each candidate and periodically adopts the most performant one.

Machine learning algorithms

With the recent rapid development of machine learning (ML), there are also a few papers that adopt ML techniques to enhance cache performance. LFO [8] and LRB [35] use ML models to learn Belady’s OPT [6], and apply the ML models to CDN (Content Delivery Networks) caches. Parrot [25] also use ML to learn Belady’s OPT from history, but uses modern deep learning architectures like Transformer [38] and BiDAF [33]. [41] utilizes a concept similar to LARC [21] that the majority of traffic is accessed just once, and uses ML models to predict whether data is worth inserting into the flash cache. The algorithm showed a large flash write reduction in Tencent’s photo cache system as well as the improvement of hit ratios and latency. LeCaR [39] uses an ML approach to adaptively decide the better policy between LRU and LFU at eviction time. Zhou and Maas [43] model the inter-arrival times of a block as a log-normal distribution and learn the parameters from traces; then the evictions are executed in the manner of Belady’s OPT: the block with lowest probability to get the next access in the near future will be evicted.

9 Conclusions

In this paper, we introduce CacheSack, an admission policy optimization for Google’s datacenter flash caches. CacheSack provides an efficient estimation for the performance metrics of an LRU-style cache under various configuration options. We use a knapsack approach to identify the optimal admission policies to minimize the total cache-operating cost. We share the experience of deploying CacheSack in Colossus Flash Cache, the general-purpose flash cache serving Colossus, which has since become the default admission policy. CacheSack requires less manual configuration than the previously used cache admission algorithm (LARC), significantly reduces disk reads and bytes written to flash, and improves TCO by 6.5% compared to LARC.

Acknowledgements

The authors would like to thank Cory Casper, Junaid Khalid, Martin Maas, and Richard McDougall for their assistance in various stages of the design and implementation of this algorithm. We would also like to thank Dan Gibson, Larry Greenfield, Aaron Laursen, Milo Martin, Damodharan Rajalingam, and John Wilkes, as well as the anonymous reviewers and our conference shepherd, for their reviews and suggestions that improved this manuscript.

A Mathematical model of CacheSack

A.1 Model assumption

CacheSack models the cache as using LRU evictions. Colossus Flash Cache considers data for caching to be immutable after being written, i.e. the first access is a write, and subsequent ones are reads; mutability is handled by higher layers in the system. The CacheSack model does not need the immutability assumption, but we keep it to align with the actual system; the model can be easily modified for the mutable case.

A.2 Metric estimation of an LRU cache

We begin with `AdmitOnMiss`. For a given block b , let $t_1, t_2, t_3, \dots, t_n$ be the read access times, and $t_0 = -\infty$ for convenience. Therefore, the inter-arrival times are $d_i = t_i - t_{i-1}$ and $d_1 = t_1 - t_0 = \infty$. Assume that D is the modeled cache retention time; that is, D is the maximum duration that a block stays in the LRU cache without any intervening accesses. We can classify the inter-arrival times as follows:

- $d_i \leq D$: A cache hit because the access arrives before the block leaves the cache. The block is moved to the head of the queue because of the LRU eviction.

- $d_i > D$: A cache miss because the access arrives after the block leaves the cache. `AdmitOnMiss` inserts the block into the cache on miss, causing a write to the cache.
- For a flash cache miss, we update the *buffer cache simulator* to see whether it is also a cache miss in the buffer cache. If so, the access is a disk read.

We can then write disk reads $S_b^{\text{AOM}}(D)$, cache byte-time usage² $U_b^{\text{AOM}}(D)$ and bytes written to cache $W_b^{\text{AOM}}(D)$ as functions of D :

$$B_b^{\text{AOM}}(D, i) = \begin{cases} 1, & \text{Buffer Cache Hit at } t_i, \text{ using AOM.} \\ 0, & \text{Buffer Cache Miss at } t_i, \text{ using AOM.} \end{cases}$$

$$S_b^{\text{AOM}}(D) = |\{i : d_i > D, B_b^{\text{AOM}}(D, i) = 0\}|,$$

$$U_b^{\text{AOM}}(D) = \text{Size}(b) \times \sum_i \min(d_i, D),$$

$$W_b^{\text{AOM}}(D) = \text{Size}(b) \times |\{i : d_i > D\}|.$$

Similarly, the metrics for a category C is the sum of the metrics for all blocks in C :

$$S_C^{\text{AOM}}(D) = \sum_{b \in C} S_b^{\text{AOM}}(D),$$

$$U_C^{\text{AOM}}(D) = \sum_{b \in C} U_b^{\text{AOM}}(D),$$

$$W_C^{\text{AOM}}(D) = \sum_{b \in C} W_b^{\text{AOM}}(D).$$

The only difference between `AdmitOnWrite` and `AdmitOnMiss` is that `AdmitOnWrite` also takes into account write accesses. Therefore, for `AdmitOnWrite`, we let t_1 be the write access time, t_2 be the first read access time, t_3 be the second read access time and so on. Then we can similarly define $S_C^{\text{AOW}}(D)$, $U_C^{\text{AOW}}(D)$ and $W_C^{\text{AOW}}(D)$.

For `AdmitOnSecondMiss`, a block is admitted at the second miss (read access). In addition, to prevent the cache from inserting a cold block, we require that when inserting a block, its last read access time must be not older than the oldest last access time of the blocks in the cache. Mathematically, a block is inserted at t_{i-1} (if not already in the cache) only if $d_{i-1} = t_{i-1} - t_{i-2} \leq D$. Therefore, the condition that a block is in the cache at t_{i-1} , either because it is already in the cache or it is inserted, is $d_{i-1} \leq D$, and so an access at t_i is a cache hit if and only if $d_{i-1} \leq D$ and $d_i \leq D$:

$$B_b^{\text{AOSM}}(D, i) = \begin{cases} 1, & \text{Buffer Cache Hit at } t_i, \text{ using AOSM.} \\ 0, & \text{Buffer Cache Miss at } t_i, \text{ using AOSM.} \end{cases}$$

$$S_b^{\text{AOSM}}(D) = |\{i : \max(d_{i-1}, d_i) > D, B_b^{\text{AOSM}}(D, i) = 0\}|.$$

For $U_b^{\text{AOSM}}(D)$, the access at t_i contributes cache usage if either it is a cache hit, $\max(d_i, d_{i-1}) \leq D$, with residence time d_i , or

²Bytes of occupied cache multiplied by seconds of residence time in cache. The same concept is also used in LHD [4].

a block insertion, $d_i \leq D < d_{i-1}$, with residence time D :

$$U_b^{\text{AOSM}}(D) = \text{Size}(b) \times \sum_i \left(d_i \times \mathbf{1}_{\{\max(d_i, d_{i-1}) \leq D\}} + D \times \mathbf{1}_{\{d_i \leq D < d_{i-1}\}} \right).$$

$W_b^{\text{AOSM}}(D)$ is the block size times the number of insertions:

$$W_b^{\text{AOSM}}(D) = \text{Size}(b) \times |\{i : d_i \leq D < d_{i-1}\}|.$$

Of course, $S_C^{\text{AOSM}}(D)$, $U_C^{\text{AOSM}}(D)$ and $W_C^{\text{AOSM}}(D)$ can be defined similarly.

Because `NeverAdmit` does not insert any blocks at all, $U_C^{\text{NA}}(D) = 0$, $W_C^{\text{NA}}(D) = 0$ and $S_C^{\text{NA}}(D)$ is the number of buffer cache misses because of the accesses to the blocks in C :

$$B_b^{\text{NA}}(D, i) = \begin{cases} 1, & \text{Buffer Cache Hit at } t_i, \text{ using NA.} \\ 0, & \text{Buffer Cache Miss at } t_i, \text{ using NA.} \end{cases}$$

$$S_b^{\text{NA}}(D) = |\{i : B_b^{\text{NA}}(D, i) = 0\}|,$$

$$S_C^{\text{NA}}(D) = \sum_{b \in C} S_b^{\text{NA}}(D).$$

A.3 Linear program

We minimize the total cost by formulating a linear program. The cost function is the sum of the cost of disk reads and the cost of written bytes:

$$V_C^p(D) = \text{Cost of } S_C^p(D) + \text{Cost of } W_C^p(D),$$

for $p \in \{\text{AOM}, \text{AOW}, \text{AOSM}, \text{NA}\}$ and a given category C .

A category can receive *fractional* admission policies. For example, `CacheSack` may decide that it is optimal to apply `AdmitOnMiss`, `AdmitOnSecondMiss`, `AdmitOnWrite` and `NeverAdmit` are applied to 30%, 20%, 10% and 40% of blocks in C , respectively. Then we can formulate a linear program that finds optimal policy fractions $\{\alpha_C^{\text{AOM}}, \alpha_C^{\text{AOW}}, \alpha_C^{\text{AOSM}}, \alpha_C^{\text{NA}}\}$ to minimize the overall cost:

$$\min_{\alpha_C^{\text{AOM}}, \alpha_C^{\text{AOW}}, \alpha_C^{\text{AOSM}}, \alpha_C^{\text{NA}}} \sum_C \left(\alpha_C^{\text{AOM}} V_C^{\text{AOM}}(D) + \alpha_C^{\text{AOSM}} V_C^{\text{AOSM}}(D) + \alpha_C^{\text{AOW}} V_C^{\text{AOW}}(D) + \alpha_C^{\text{NA}} V_C^{\text{NA}}(D) \right), \quad (1)$$

subject to the capacity constraint that the cache usage should not exceed the given cache capacity U_{total} :

$$\begin{aligned} 0 \leq \alpha_C^{\text{AOM}}, \alpha_C^{\text{AOW}}, \alpha_C^{\text{AOSM}}, \alpha_C^{\text{NA}} \leq 1, \\ \alpha_C^{\text{AOM}} + \alpha_C^{\text{AOW}} + \alpha_C^{\text{AOSM}} + \alpha_C^{\text{NA}} = 1, \\ \sum_C \left(\alpha_C^{\text{AOM}} U_C^{\text{AOM}}(D) + \alpha_C^{\text{AOSM}} U_C^{\text{AOSM}}(D) + \alpha_C^{\text{AOW}} U_C^{\text{AOW}}(D) + \alpha_C^{\text{NA}} U_C^{\text{NA}}(D) \right) \leq U_{\text{total}}. \end{aligned}$$

We note that if the LRU cache is perfectly modeled by the approach in Section A.2, the resulting cache retention time of the LRU cache is exactly D after applying the optimal policy fractions.

Figure 16: Example of Andrew’s monotone chain convex hull algorithm applied to the admission policies.

A.4 Greedy algorithm

Although the linear program (1) can be solved by a standard solver, we are able to solve it by a greedy algorithm with a simple transformation. It is especially beneficial for the production deployment because of the low-overhead and stability of the greedy algorithm, compared to a generic solver. We first note that the difference between the above linear program and a fractional knapsack problem [14] is that for each category, we need to decide *coupled* four fractions (three degrees of freedom), instead of two fractions (one degree of freedom) in a fractional knapsack problem. Thus, the greedy algorithm in [14] can not be directly applied. However, we can use Andrew’s lower convex hull algorithm [2] to decouple the dependency.

For a given category C , the lower convex hull formed by the points $\{(U_C^p, V_C^p), p \in \{\text{AOM}, \text{AOW}, \text{AOSM}, \text{NA}\}\}$, is the lowest cost of C that can be generated among all convex combinations of the policies. For example, Figure 16 is the lower convex hull constructed by the given admission policies by using Andrew’s algorithm. Let $F_C(u)$ denote the lower convex hull formed above, as a mapping from cache usage u to the corresponding cost, for each category C . By dropping any line segments with non-negative slopes, all F_C are strictly decreasing, piecewise linear functions. Then we can transform the linear program to a convex optimization problem:

$$\min_{u_C \geq 0} \sum_C F_C(u_C), \quad \sum_C u_C \leq U_{\text{total}}.$$

We can then solve the above convex optimization problem by the steepest descent method (a greedy algorithm). We initialize $u_C = 0$ for all C and iteratively decide each u_C in the following way. We first choose the line segment with the most negative slope among all line segments of F_C and change the value of the corresponding u_C . In the same fashion, we

then choose the line segment with second most negative slope and change the value of the corresponding u_C , then the third most negative slope, and so on, until the sum of u_C reaches U_{total} .

Because we allow fractional policies, the category corresponding to the last chosen line segment generally has the optimal policy as a convex combination of two of $\{\text{AOM}, \text{AOW}, \text{AOSM}, \text{NA}\}$, and the optimal policy of any other category must be exactly one of $\{\text{AOM}, \text{AOW}, \text{AOSM}, \text{NA}\}$.

A.5 Optimization over modeled cache retention times

The linear program (1) is to find the optimal policy fractions for a *given* modeled cache retention time D , which can not be known *a priori*. Thus, we need to solve the same optimization problem for *all* possible D :

$$\min_{D>0} \min_{\alpha_C^{\text{AOM}}, \alpha_C^{\text{AOW}}, \alpha_C^{\text{AOSM}}, \alpha_C^{\text{NA}}} \sum_C \left(\alpha_C^{\text{AOM}} v_C^{\text{AOM}}(D) + \alpha_C^{\text{AOSM}} v_C^{\text{AOSM}}(D) + \alpha_C^{\text{AOW}} v_C^{\text{AOW}}(D) + \alpha_C^{\text{NA}} v_C^{\text{NA}}(D) \right),$$

subject to the same capacity constraint.

To do this, we can use a standard scalar-variable optimization approach like Brent’s method [10] for $0 < D \leq \mathbf{D}$, where \mathbf{D} is a suitable upper bound. A brute-force approach may be even more practical for implementation: we simply solve the optimization problem for a set of reasonable retention times: $0 < D_1 < D_2 < \dots < D_m = \mathbf{D}$.

Amazon Web Services

Abstract

Amazon DynamoDB is a NoSQL cloud database service that provides consistent performance at any scale. Hundreds of thousands of customers rely on DynamoDB for its fundamental properties: consistent performance, availability, durability, and a fully managed serverless experience. In 2021, during the 66-hour Amazon Prime Day shopping event, Amazon systems - including Alexa, the Amazon.com sites, and Amazon fulfillment centers, made trillions of API calls to DynamoDB, peaking at 89.2 million requests per second, while experiencing high availability with single-digit millisecond performance. Since the launch of DynamoDB in 2012, its design and implementation have evolved in response to our experiences operating it. The system has successfully dealt with issues related to fairness, traffic imbalance across partitions, monitoring, and automated system operations without impacting availability or performance. Reliability is essential, as even the slightest disruption can significantly impact customers. This paper presents our experience operating DynamoDB at a massive scale and how the architecture continues to evolve to meet the ever-increasing demands of customer workloads.

1 Introduction

Amazon DynamoDB is a NoSQL cloud database service that supports fast and predictable performance at any scale. DynamoDB is a foundational AWS service that serves hundreds of thousands of customers using a massive number of servers located in data centers around the world. DynamoDB powers multiple high-traffic Amazon properties and systems including Alexa, the Amazon.com sites, and all Amazon fulfillment centers. Moreover, many AWS services such as AWS Lambda, AWS Lake Formation, and Amazon SageMaker are built on DynamoDB, as well as hundreds of thousands of customer applications.

These applications and services have demanding operational requirements with respect to performance, reliability, durability, efficiency, and scale. The users of DynamoDB rely

on its ability to serve requests with consistent low latency. For DynamoDB customers, consistent performance at any scale is often more important than median request service times because unexpectedly high latency requests can amplify through higher layers of applications that depend on DynamoDB and lead to a bad customer experience. The goal of the design of DynamoDB is to complete *all* requests with low single-digit millisecond latencies. In addition, the large and diverse set of customers who use DynamoDB rely on an ever-expanding feature set as shown in Figure 1. As DynamoDB has evolved over the last ten years, a key challenge has been adding features without impacting operational requirements. To benefit customers and application developers, DynamoDB uniquely integrates the following six fundamental system properties:

DynamoDB is a fully managed cloud service. Using the DynamoDB API, applications create tables and read and write data without regard for where those tables are stored or how they're managed. DynamoDB frees developers from the burden of patching software, managing hardware, configuring a distributed database cluster, and managing ongoing cluster operations. DynamoDB handles resource provisioning, automatically recovers from failures, encrypts data, manages software upgrades, performs backups, and accomplishes other tasks required of a fully-managed service.

DynamoDB employs a multi-tenant architecture. DynamoDB stores data from different customers on the same physical machines to ensure high utilization of resources, enabling us to pass the cost savings to our customers. Resource reservations, tight provisioning, and monitored usage provide isolation between the workloads of co-resident tables.

DynamoDB achieves boundless scale for tables. There are no predefined limits for the amount of data each table can store. Tables grow elastically to meet the demand of the customers' applications. DynamoDB is designed to scale the resources dedicated to a table from several servers to many thousands as needed. DynamoDB spreads an application's data across more servers as the amount of data storage and the demand for throughput requirements grow.

DynamoDB provides predictable performance. The simple

Figure 1: DynamoDB yimeline

DynamoDB API with *GetItem* and *PutItem* operations allows it to respond to requests with consistent low latency. An application running in the same AWS Region as its data will typically see average service-side latencies in the low single-digit millisecond range for a 1 KB item. Most importantly, DynamoDB latencies are predictable. Even as tables grow from a few megabytes to hundreds of terabytes, latencies remain stable due to the distributed nature of data placement and request routing algorithms in DynamoDB. DynamoDB handles any level of traffic through horizontal scaling and automatically partitions and re-partitions data to meet an application’s I/O performance requirements.

DynamoDB is highly available. DynamoDB replicates data across multiple data centers—called Availability Zones in AWS—and automatically re-replicates in the case of disk or node failures to meet stringent availability and durability requirements. Customers can also create global tables that are geo-replicated across selected Regions for disaster recovery and provide low latency access from anywhere. DynamoDB offers an availability SLA of 99.99 for regular tables and 99.999 for global tables (where DynamoDB replicates across tables across multiple AWS Regions).

DynamoDB supports flexible use cases. DynamoDB doesn’t force developers into a particular data model or consistency model. DynamoDB tables don’t have a fixed schema but instead allow each data item to contain any number of attributes with varying types, including multi-valued attributes. Tables use a key-value or document data model. Developers can request strong or eventual consistency when reading items from a table.

In this paper, we describe how DynamoDB evolved as a distributed database service to meet the needs of its customers without losing its key aspect of providing a single-tenant experience to every customer using a multi-tenant architecture. The paper explains the challenges faced by the system and how the service evolved to handle those challenges while connecting the required changes to a common theme of durability, availability, scalability, and predictable performance.

The paper captures the following lessons that we have learnt over the years

- Adapting to customers’ traffic patterns to reshape the physical partitioning scheme of the database tables improves customer experience.

- Performing continuous verification of data-at-rest is a reliable way to protect against both hardware failures and software bugs in order to meet high durability goals.
- Maintaining high availability as a system evolves requires careful operational discipline and tooling. Mechanisms such as formal proofs of complex algorithms, game days (chaos and load tests), upgrade/downgrade tests, and deployment safety provides the freedom to safely adjust and experiment with the code without the fear of compromising correctness.
- Designing systems for predictability over absolute efficiency improves system stability. While components such as caches can improve performance, do not allow them to hide the work that would be performed in their absence, ensuring that the system is always provisioned to handle the unexpected.

The structure of this paper is as follows: Section 2 expands on the history of DynamoDB and explains its origins, which derive from the original Dynamo system. Section 3 presents the architectural overview of DynamoDB. Section 4 covers the journey of DynamoDB from provisioned to on-demand tables. Section 5 covers how DynamoDB ensures strong durability. Section 6 describes the availability challenges faced and how these challenges were handled. Section 7 provides some experimental results based on the Yahoo! Cloud Serving Benchmark (YCSB) benchmarks, and Section 8 concludes the paper.

2 History

The design of DynamoDB was motivated by our experiences with its predecessor Dynamo [9], which was the first NoSQL database system developed at Amazon. Dynamo was created in response to the need for a highly scalable, available, and durable key-value database for shopping cart data. In the early years, Amazon learned that providing applications with direct access to traditional enterprise database instances led to scaling bottlenecks such as connection management, interference between concurrent workloads, and operational problems with tasks such as schema upgrades. Thus, a service-oriented architecture was adopted to encapsulate an application’s data

behind service-level APIs that allowed sufficient decoupling to address tasks like reconfiguration without having to disrupt clients.

High availability is a critical property of a database service as any downtime can impact customers that depend on the data. Another critical requirement for Dynamo was predictable performance so that applications could provide a consistent experience to their users. To achieve these goals, Amazon had to start from first principles when designing Dynamo. The adoption of Dynamo widened to serve several use cases within Amazon because it was the only database service that provided high reliability at scale. However, Dynamo still carried the operational complexity of self-managed large database systems. Dynamo was a single-tenant system and teams were responsible for managing their own Dynamo installations. Teams had to become experts on various parts of the database service and the resulting operational complexity became a barrier to adoption.

During this period, Amazon launched new services (notably Amazon S3 and Amazon SimpleDB) that focused on a managed and elastic experience in order to remove this operational burden. Amazon engineers preferred to use these services instead of managing their own systems like Dynamo, even though the functionality of Dynamo was often better aligned with their applications' needs. Managed elastic services freed developers from administrating databases and allowed them to focus on their applications.

The first database-as-a-service from Amazon was SimpleDB [1], a fully managed elastic NoSQL database service. SimpleDB provided multi-datacenter replication, high availability, and high durability without the need for customers to set up, configure, or patch their database. Like Dynamo, SimpleDB also had a very simple table interface with a restricted query set that served as a building block for many developers. While SimpleDB was successful and powered many applications, it had some limitations. One limitation was that tables had a small capacity in terms of storage (10GB) and of request throughput. Another limitation was the unpredictable query and write latencies, which stemmed from the fact that all table attributes were indexed, and the index needed to be updated with every write. These limitations created a new kind of operational burden for developers. They had to divide data between multiple tables to meet their application's storage and throughput requirements.

We realized that the goal of removing the limitations of SimpleDB and providing a scalable NoSQL database service with predictable performance could not be met with the SimpleDB APIs. We concluded that a better solution would combine the best parts of the original Dynamo design (incremental scalability and predictable high performance) with the best parts of SimpleDB (ease of administration of a cloud service, consistency, and a table-based data model that is richer than a pure key-value store). These architectural discussions culminated in Amazon DynamoDB, a public service launched in 2012

| Operation | Description |
|------------|--|
| PutItem | Inserts a new item, or replaces an old item with a new item. |
| UpdateItem | Updates an existing item, or adds a new item to the table if it doesn't already exist. |
| DeleteItem | The DeleteItem operation deletes a single item from the table by the primary key. |
| GetItem | The GetItem operation returns a set of attributes for the item with the given primary key. |

Table 1: DynamoDB CRUD APIs for items

that shared most of the name of the previous Dynamo system but little of its architecture. Amazon DynamoDB was the result of everything we'd learned from building large-scale, non-relational databases for Amazon.com and has evolved based on our experiences building highly scalable and reliable cloud computing services at AWS.

3 Architecture

A DynamoDB table is a collection of items, and each item is a collection of attributes. Each item is uniquely identified by a primary key. The schema of the primary key is specified at the table creation time. The primary key schema contains a partition key or a partition and sort key (a composite primary key). The partition key's value is always used as an input to an internal hash function. The output from the hash function and the sort key value (if present) determines where the item will be stored. Multiple items can have the same partition key value in a table with a composite primary key. However, those items must have different sort key values.

DynamoDB also supports secondary indexes to provide enhanced querying capability. A table can have one or more secondary indexes. A secondary index allows querying the data in the table using an alternate key, in addition to queries against the primary key. DynamoDB provides a simple interface to store or retrieve items from a table or an index. Table 1 contains the primary operations available to clients for reading and writing items in DynamoDB tables. Any operation that inserts, updates, or deletes an item can be specified with a condition that must be satisfied in order for the operation to succeed. DynamoDB supports ACID transactions enabling applications to update multiple items while ensuring atomicity, consistency, isolation, and durability (ACID) across items without compromising the scalability, availability, and performance characteristics of DynamoDB tables.

A DynamoDB table is divided into multiple partitions to handle the throughput and storage requirements of the table. Each partition of the table hosts a disjoint and contiguous part of the table's key-range. Each partition has multiple replicas distributed across different Availability Zones for high avail-

Figure 2: Storage replica on a storage node

Figure 3: Log replica on a log node

ability and durability. The replicas for a partition form a replication group. The replication group uses Multi-Paxos [14] for leader election and consensus. Any replica can trigger a round of the election. Once elected leader, a replica can maintain leadership as long as it periodically renews its leadership lease.

Only the leader replica can serve write and strongly consistent read requests. Upon receiving a write request, the leader of the replication group for the key being written generates a write-ahead log record and sends it to its peer (replicas). A write is acknowledged to the application once a quorum of peers persists the log record to their local write-ahead logs. DynamoDB supports strongly and eventually consistent reads. Any replica of the replication group can serve eventually consistent reads. The leader of the group extends its leadership using a lease mechanism. If the leader of the group is failure detected (considered unhealthy or unavailable) by any of its peers, the peer can propose a new round of the election to elect itself as the new leader. The new leader won't serve any writes or consistent reads until the previous leader's lease expires.

A replication group consists of storage replicas that contain both the write-ahead logs and the B-tree that stores the key-value data as shown in Figure 2. To improve availability and durability, a replication group can also contain replicas that only persist recent write-ahead log entries as shown in Figure 3. These replicas are called *log replicas*. Log replicas are akin to acceptors in Paxos. Log replicas do not store key-value data. Section 5 and 6 discusses how *log replicas* help DynamoDB improve its availability and durability.

DynamoDB consists of tens of microservices. Some of the core services in DynamoDB are the metadata service, the

Figure 4: DynamoDB architecture

request routing service, the storage nodes, and the autoadmin service, as shown in Figure 4. The metadata service stores routing information about the tables, indexes, and replication groups for keys for a given table or index. The request routing service is responsible for authorizing, authenticating, and routing each request to the appropriate server. For example, all read and update requests are routed to the storage nodes hosting the customer data. The request routers look up the routing information from the metadata service. All resource creation, update, and data definition requests are routed to the autoadmin service. The storage service is responsible for storing customer data on a fleet of storage nodes. Each of the storage nodes hosts many replicas of different partitions.

The autoadmin service is built to be the central nervous system of DynamoDB. It is responsible for fleet health, partition health, scaling of tables, and execution of all control plane requests. The service continuously monitors the health of all the partitions and replaces any replicas deemed unhealthy (slow or not responsive or being hosted on bad hardware). The service also performs health checks of all core components of DynamoDB and replaces any hardware that is failing or has failed. For example, if the autoadmin service detects a storage node to be unhealthy, it kicks off a recovery process that replaces the replicas hosted on that node to bring the system back to a stable state.

Other DynamoDB services not shown in in Figure 4 support features such as point-in-time restore, on-demand backups, update streams, global admission control, global tables, global secondary indices, and transactions.

4 Journey from provisioned to on-demand

When DynamoDB launched, we introduced an internal abstraction, partitions, as a way to dynamically scale both the capacity and performance of tables. In the original DynamoDB release, customers explicitly specified the throughput that a table required in terms of read capacity units (RCUs) and write capacity units (WCUs). For items up to 4 KB in size, one RCU can perform one strongly consistent read request per second. For items up to 1 KB in size, one WCU can

perform one standard write request per second. RCUs and WCUs collectively are called provisioned throughput. The original system split a table into partitions that allow its contents to be spread across multiple storage nodes and mapped to both the available space and performance on those nodes. As the demands from a table changed (because it grew in size or because the load increased), partitions could be further split and migrated to allow the table to scale elastically. Partition abstraction proved to be really valuable and continues to be central to the design of DynamoDB. However this early version tightly coupled the assignment of both capacity and performance to individual partitions, which led to challenges.

DynamoDB uses admission control to ensure that storage nodes don't become overloaded, to avoid interference between co-resident table partitions, and to enforce the throughput limits requested by customers. Admission control in DynamoDB has evolved over the past decade. Admission control was the shared responsibility of all storage nodes for a table. Storage nodes independently performed admission control based on the allocations of their locally stored partitions. Given that a storage node hosts partitions from multiple tables, the allocated throughput of each partition was used to isolate the workloads. DynamoDB enforced a cap on the maximum throughput that could be allocated to a single partition, and ensured that the total throughput of all the partitions hosted by a storage node is less than or equal to the maximum allowed throughput on the node as determined by the physical characteristics of its storage drives.

The throughput allocated to partitions was adjusted when the overall table's throughput was changed or its partitions were split into child partitions. When a partition was split for size, the allocated throughput of the parent partition was equally divided among the child partitions. When a partition was split for throughput, the new partitions were allocated throughput based on the table's provisioned throughput. For example, assume that a partition can accommodate a maximum provisioned throughput of 1000 WCUs. When a table is created with 3200 WCUs, DynamoDB created four partitions that each would be allocated 800 WCUs. If the table's provisioned throughput was increased to 3600 WCUs, then each partition's capacity would increase to 900 WCUs. If the table's provisioned throughput was increased to 6000 WCUs, then the partitions would be split to create eight child partitions, and each partition would be allocated 750 WCUs. If the table's capacity was decreased to 5000 WCUs, then each partition's capacity would be decreased to 675 WCUs.

The uniform distribution of throughput across partitions is based on the assumptions that an application uniformly accesses keys in a table and the splitting a partition for size equally splits the performance. However, we discovered that application workloads frequently have non-uniform access patterns both over time and over key ranges. When the request rate within a table is non-uniform, splitting a partition and dividing performance allocation proportionately can result

in the *hot* portion of the partition having less available performance than it did before the split. Since throughput was allocated statically and enforced at a partition level, these non-uniform workloads occasionally resulted in an application's reads and writes being rejected, called throttling, even though the total provisioned throughput of the table was sufficient to meet its needs.

Two most commonly faced challenges by the applications were: *hot partitions* and *throughput dilution*. Hot partitions arose in applications that had traffic going consistently towards a few items of their tables. The hot items could belong to a stable set of partitions or could hop around to different partitions over time. Throughput dilution was common for tables where partitions were split for size. Splitting a partition for size would cause the throughput of the partition to be divided equally among the newly created child partitions, and hence the per partition throughput would decrease.

In both cases, from the customer's perspective, throttling caused their application to experience periods of unavailability even though the service was behaving as expected. Customers who experienced throttling would work around it by increasing a table's provisioned throughput and not use all the capacity. That is, tables would be over-provisioned. While this allowed them to achieve the performance they needed, it was a poor experience because it was difficult to estimate the right level of performance provisioning for their tables.

4.1 Initial improvements to admission control

As we mentioned at the start of this section, hot partitions and throughput dilution stemmed from tightly coupling a rigid performance allocation to each partition, and dividing that allocation as partitions split. We liked that enforcing allocations at an individual partition level avoided the need for the complexities of distributed admission control, but it became clear these controls weren't sufficient. Shortly after launching, DynamoDB introduced two improvements, bursting and adaptive capacity, to address these concerns.

4.1.1 Bursting

The key observation that partitions had non-uniform access also led us to observe that not all partitions hosted by a storage node used their allocated throughput simultaneously. Hence, to absorb temporal spikes in workloads at a partition level, DynamoDB introduced the concept of bursting. The idea behind bursting was to let applications tap into the unused capacity at a partition level on a best effort basis to absorb short-lived spikes. DynamoDB retained a portion of a partition's unused capacity for later bursts of throughput usage for up to 300 seconds and utilized it when consumed capacity exceeded the provisioned capacity of the partition. The unused capacity is called *burst* capacity.

DynamoDB still maintained workload isolation by ensuring

that a partition could only burst if there was unused throughput at the node level. The capacity was managed on the storage node using multiple token buckets: two for each partition (allocated and burst) and one for the node. These buckets provided admission control. When a read or write request arrived on a storage node, if there were tokens in the partition's allocated token bucket, then the request was admitted and tokens were deducted from the partition and node level bucket. Once a partition had exhausted all the provisioned tokens, requests were allowed to burst only when tokens were available both in the burst token bucket and the node level token bucket. Read requests were accepted based on the local token buckets. Write requests using burst capacity required an additional check on the node-level token bucket of other member replicas of the partition. The leader replica of the partition periodically collected information about each of the members node-level capacity. In section 4.3 we explain how we increased a node's ability to burst.

4.1.2 Adaptive capacity

DynamoDB launched adaptive capacity to better absorb long-lived spikes that cannot be absorbed by the burst capacity. Adaptive capacity allowed DynamoDB to better absorb workloads that had heavily skewed access patterns across partitions. Adaptive capacity actively monitored the provisioned and consumed capacity of all the tables. If a table experienced throttling and the table level throughput was not exceeded, then it would automatically increase (boost) the allocated throughput of the partitions of the table using a proportional control algorithm. If the table was consuming more than its provisioned capacity then capacity of the partitions which received the boost would be decreased. The autoadmin system ensured that partitions receiving boost were relocated to an appropriate node that had the capacity to serve the increased throughput, however like bursting, adaptive capacity was also best-effort but eliminated over 99.99% of the throttling due to skewed access pattern.

4.2 Global admission control

Even though DynamoDB had substantially reduced the throughput problem for non-uniform access using bursting and adaptive capacity, both the solutions had limitations. Bursting was only helpful for short-lived spikes in traffic and it was dependent on the node having throughput to support bursting. Adaptive capacity was reactive and kicked in only after throttling had been observed. This meant that the application using the table had already experienced brief period of unavailability. The salient takeaway from bursting and adaptive capacity was that we had tightly coupled partition level capacity to admission control. Admission control was distributed and performed at a partition level. DynamoDB realized it would going to be beneficial to remove admission

control from the partition and let the partition burst *always* while providing workload isolation.

To solve the problem of admission control, DynamoDB replaced adaptive capacity with global admission control (GAC). GAC builds on the same idea of token buckets. The GAC service centrally tracks the total consumption of the table capacity in terms of tokens. Each request router maintains a local token bucket to make admission decisions and communicates with GAC to replenish tokens at regular intervals (in the order of few seconds). GAC maintains an ephemeral state computed on the fly from client requests. Each GAC server can be stopped and restarted without any impact on the overall operation of the service. Each GAC server can track one or more token buckets configured independently. All the GAC servers are part of an independent hash ring. Request routers manage several time-limited tokens locally. When a request from the application arrives, the request router deducts tokens. Eventually, the request router will run out of tokens because of consumption or expiry. When the request router runs of tokens, it requests more tokens from GAC. The GAC instance uses the information provided by the client to estimate the global token consumption and vends tokens available for the next time unit to the client's share of overall tokens. Thus, it ensures that non-uniform workloads that send traffic to only a subset of items can execute up to the maximum partition capacity.

In addition to the global admission control scheme, the partition-level token buckets were retained for defense-in-depth. The capacity of these token buckets is then capped to ensure that one application doesn't consume all or a significant share of the resources on the storage nodes.

4.3 Balancing consumed capacity

Letting partitions always burst required DynamoDB to manage burst capacity effectively. DynamoDB runs on a variety of hardware instance types. These instance types vary by throughput and storage capabilities. The latest generation of storage nodes hosts thousands of partition replicas. The partitions hosted on a single storage node could be wholly unrelated and belong to different tables. Hosting replicas from multiple tables on a storage node, where each table could be from a different customer and have varied traffic patterns involves defining an allocation scheme that decides which replicas can safely co-exist without violating critical properties such as availability, predictable performance, security, and elasticity.

Colocation was a straightforward problem with provisioned throughput tables. Colocation was more manageable in the provisioned mode because of static partitions. Static partitions made the allocation scheme reasonably simple. In the case of provisioned tables without bursting and adaptive capacity, allocation involved finding storage nodes that could accommodate a partition based on its allocated capacity. Partitions

were never allowed to take more traffic than their allocated capacity and, hence there were no noisy neighbors. All partitions on a storage node did not utilize their total capacity at a given instance. Bursting when trying to react to the changing workload meant that the storage node might go above its prescribed capacity and thus made the colocation of tenants a more complex challenge. Thus, the system packed storage nodes with a set of replicas greater than the node's overall provisioned capacity. DynamoDB implemented a system to proactively balance the partitions allocated across the storage nodes based on throughput consumption and storage to mitigate availability risks caused by tightly packed replicas. Each storage node independently monitors the overall throughput and data size of all its hosted replicas. In case the throughput is beyond a threshold percentage of the maximum capacity of the node, it reports to the autoadmin service a list of candidate partition replicas to move from the current node. The autoadmin finds a new storage node for the partition in the same or another Availability Zone that doesn't have a replica of this partition.

4.4 Splitting for consumption

Even with GAC and the ability for partitions to burst always, tables could experience throttling if their traffic was skewed to a specific set of items. To address this problem, DynamoDB automatically scales out partitions based on the throughput consumed. Once the consumed throughput of a partition crosses a certain threshold, the partition is split for consumption. The split point in the key range is chosen based on key distribution the partition has observed. The observed key distribution serves as a proxy for the application's access pattern and is more effective than splitting the key range in the middle. Partition splits usually complete in the order of minutes. There are still class of workloads that cannot benefit from split for consumption. For example, a partition receiving high traffic to a single item or a partition where the key range is accessed sequentially will not benefit from split. DynamoDB detects such access patterns and avoids splitting the partition.

4.5 On-demand provisioning

Many applications that migrated to DynamoDB previously ran on-premises or on self-hosted databases. In either scenario, the application developer had to provision servers. DynamoDB provides a simplified serverless operational model and a new model for provisioning - read and write capacity units. Because the concept of capacity units was new to customers, some found it challenging to forecast the provisioned throughput. As mentioned in the beginning of this section, customers either over provisioned, which resulted in low utilization or under provisioned which resulted in throttles. To improve the customer experience for spiky workloads, we

launched on-demand tables. On-demand tables remove the burden from our customers of figuring out the right provisioning for tables. DynamoDB provisions the on-demand tables based on the consumed capacity by collecting the signal of reads and writes and instantly accommodates up to double the previous peak traffic on the table. If an application needs more than double the previous peak on table, DynamoDB automatically allocates more capacity as the traffic volume increases to ensure that the workload does not experience throttling. On-demand scales a table by splitting partitions for consumption. The split decision algorithm is based on traffic. GAC allows DynamoDB to monitor and protect the system from one application consuming all the resources. The ability to balance based on consumed capacity effectively means partitions of on-demand tables can be placed intelligently so as to not run into node level limits.

5 Durability and correctness

Data should never be lost after it has been committed. In practice, data loss can occur because of hardware failures, software bugs, or hardware bugs. DynamoDB is designed for high durability by having mechanisms to prevent, detect, and correct any potential data losses.

5.1 Hardware failures

As with most database management systems, the write-ahead logs [15] in DynamoDB are central for providing durability and crash recovery. Write ahead logs are stored in all three replicas of a partition. For higher durability, the write ahead logs are periodically archived to S3, an object store that is designed for 11 nines of durability. Each replica still contains the most recent write-ahead logs that are usually waiting to be archived. The unarchived logs are typically a few hundred megabytes in size. In a large service, hardware failures such as memory and disk failures are common. When a node fails, all replication groups hosted on the node are down to two copies. The process of healing a storage replica can take several minutes because the repair process involves copying the B-tree and write-ahead logs. Upon detecting an unhealthy storage replica, the leader of a replication group adds a log replica to ensure there is no impact on durability. Adding a log replica takes only a few seconds because the system has to copy only the recent write-ahead logs from a healthy replica to the new replica without the B-tree. Thus, quick healing of impacted replication groups using log replicas ensures high durability of most recent writes.

5.2 Silent data errors

Some hardware failures can cause incorrect data to be stored [5, 7]. In our experience, these errors can happen because of the storage media, CPU, or memory [5]. Unfortunately, it's

very difficult to detect these and they can happen anywhere in the system. DynamoDB makes extensive use of checksums to detect silent errors. By maintaining checksums within every log entry, message, and log file, DynamoDB validates data integrity for every data transfer between two nodes. These checksums serve as guardrails to prevent errors from spreading to the rest of the system. For example, a checksum is computed for every message between nodes or components and is verified because these messages can go through various layers of transformations before they reach their destination. Without such checks, any of the layers could introduce a silent error.

Every log file that is archived to S3 has a manifest that contains information about the log, such as a table, partition and start and end markers for the data stored in the log file. The agent responsible for archiving log files to S3 performs various checks before uploading the data. These include and are not limited to verification of every log entry to ensure that it belongs to the correct table and partition, verification of checksums to detect any silent errors, and verification that the log file doesn't have any holes in the sequence numbers. Once all the checks are passed, the log file and its manifest are archived. Log archival agents run on all three replicas of the replication group. If one of the agents finds that a log file is already archived, the agent downloads the uploaded file to verify the integrity of the data by comparing it with its local write-ahead log. Every log file and manifest file are uploaded to S3 with a content checksum. The content checksum is checked by S3 as part of the put operation, which guards against any errors during data transit to S3.

5.3 Continuous verification

DynamoDB also continuously verifies data at rest. Our goal is to detect any silent data errors or bit rot in the system. An example of such a continuous verification system is the *scrub* process. The goal of scrub is to detect errors that we had not anticipated, such as bit rot. The scrub process runs and verifies two things: all three copies of the replicas in a replication group have the same data, and the data of the live replicas matches with a copy of a replica built offline using the archived write-ahead log entries. The process of building a replica using archived logs is explained in section 5.5 below. The verification is done by computing the checksum of the live replica and matching that with a snapshot of one generated from the log entries archived in S3. The scrub mechanism acts as a defense in depth to detect divergences between the live storage replicas with the replicas built using the history of logs from the inception of the table. These comprehensive checks have been very beneficial in providing confidence in the running system. A similar technique of continuous verification is used to verify replicas of global tables. Over the years, we have learned that continuous verification of data-at-rest is the most reliable method of protecting against hardware

failures, silent data corruption, and even software bugs.

5.4 Software bugs

DynamoDB is a distributed key-value store that's built on a complex substrate. High complexity increases the probability of human error in design, code, and operations. Errors in the system could cause loss or corruption of data, or violate other interface contracts that our customers depend on. We use formal methods [16] extensively to ensure the correctness of our replication protocols. The core replication protocol was specified using TLA+ [12, 13]. When new features that affect the replication protocol are added, they are incorporated into the specification and model checked. Model checking has allowed us to catch subtle bugs that could have led to durability and correctness issues before the code went into production. Other services such as S3 [6] have also found model-checking useful in similar scenarios.

We also employ extensive failure injection testing and stress testing to ensure the correctness of every piece of software deployed. In addition to testing and verifying the replication protocol of the data plane, formal methods have also been used to verify the correctness of our control plane and features such as distributed transactions.

5.5 Backups and restores

In addition to guarding against physical media corruption, DynamoDB also supports backup and restore to protect against any logical corruption due to a bug in a customer's application. Backups or restores don't affect performance or availability of the table as they are built using the write-ahead logs that are archived in S3. The backups are consistent across multiple partitions up to the nearest second. The backups are full copies of DynamoDB tables and are stored in an Amazon S3 bucket. Data from a backup can be restored to a new DynamoDB table at any time.

DynamoDB also supports point-in-time restore. Using point-in-time restore, customers can restore the contents of a table that existed at any time in the previous 35 days to a different DynamoDB table in the same region. For tables with the point-in-time restore enabled, DynamoDB creates periodic snapshots of the partitions that belong to the table and uploads them to S3. The periodicity at which a partition is snapshotted is decided based on the amount of write-ahead logs accumulated for the partition. The snapshots, in conjunction to write-ahead logs, are used to do point-in-time restore. When a point-in-time restore is requested for a table, DynamoDB identifies the closest snapshots to the requested time for all the partitions of the tables, applies the logs up to the timestamp in the restore request, creates a snapshot of the table, and restores it.

6 Availability

To achieve high availability, DynamoDB tables are distributed and replicated across multiple Availability Zones (AZ) in a Region. DynamoDB regularly tests resilience to node, rack, and AZ failures. For example, to test the availability and durability of the overall service, power-off tests are exercised. Using realistic simulated traffic, random nodes are powered off using a job scheduler. At the end of all the power-off tests, the test tools verify that the data stored in the database is logically valid and not corrupted. This section expands on some of the challenges solved in the last decade to ensure high availability.

6.1 Write and consistent read availability

A partition's write availability depends on its ability to have a healthy leader and a healthy write quorum. A healthy write quorum in the case of DynamoDB consists of two out of the three replicas from different AZs. A partition remains available as long as there are enough healthy replicas for a write quorum and a leader. A partition will become unavailable for writes if the number of replicas needed to achieve the minimum quorum are unavailable. If one of the replicas is unresponsive, the leader adds a log replica to the group. Adding a log replica is the fastest way to ensure that the write quorum of the group is always met. This minimizes disruption to write availability due to an unhealthy write quorum. The leader replica serves consistent reads. Introducing log replicas was a big change to the system, and the formally proven implementation of Paxos provided us the confidence to safely tweak and experiment with the system to achieve higher availability. We have been able to run millions of Paxos groups in a Region with log replicas. Eventually consistent reads can be served by any of the replicas. In case a leader replica fails, other replicas detect its failure and elect a new leader to minimize disruptions to the availability of consistent reads.

6.2 Failure detection

A newly elected leader will have to wait for the expiry of the old leader's lease before serving any traffic. While this only takes a couple of seconds, the elected leader cannot accept any new writes or consistent read traffic during that period, thus disrupting availability. One of the critical components for a highly available system is failure detection for the leader. Failure detection must be quick and robust to minimize disruptions. False positives in failure detection can lead to more disruptions in availability. Failure detection works well for failure scenarios where every replica of the group loses connection to the leader. However, nodes can experience gray network failures. Gray network failures can happen because of communication issues between a leader and follower, is-

ues with outbound or inbound communication of a node, or front-end routers facing communication issues with the leader even though the leader and followers can communicate with each other. Gray failures can disrupt availability because there might be a false positive in failure detection or no failure detection. For example, a replica that isn't receiving heartbeats from a leader will try to elect a new leader. As mentioned in the section above, this can disrupt availability. To solve the availability problem caused by gray failures, a follower that wants to trigger a failover sends a message to other replicas in the replication group asking if they can communicate with the leader. If replicas respond with a healthy leader message, the follower drops its attempt to trigger a leader election. This change in the failure detection algorithm used by DynamoDB significantly minimized the number of false positives in the system, and hence the number of spurious leader elections.

6.3 Measuring availability

DynamoDB is designed for 99.999 percent availability for global tables and 99.99 percent availability for Regional tables. Availability is calculated for each 5-minute interval as the percentage of requests processed by DynamoDB that succeed. To ensure these goals are being met, DynamoDB continuously monitors availability at service and table levels. The tracked availability data is used to analyze customer perceived availability trends and trigger alarms if customers see errors above a certain threshold. These alarms are called customer-facing alarms (CFA). The goal of these alarms is to report any availability-related problems and proactively mitigate the problem either automatically or through operator intervention. In addition to real-time tracking, the system runs daily jobs that trigger aggregation to calculate aggregate availability metrics per customer. The results of the aggregation are uploaded to S3 for regular analysis of availability trends.

DynamoDB also measures and alarms on availability observed on the client-side. There are two sets of clients used to measure the user-perceived availability. The first set of clients are internal Amazon services using DynamoDB as the data store. These services share the availability metrics for DynamoDB API calls as observed by their software. The second set of clients is our DynamoDB canary applications. These applications are run from every AZ in the Region, and they talk to DynamoDB through every public endpoint. Real application traffic allows us to reason about DynamoDB availability and latencies as seen by our customers and catch gray failures [10, 11]. They are a good representation of what our customers might be experiencing both as long and short-term trends.

6.4 Deployments

Unlike a traditional relational database, DynamoDB takes care of deployments without the need for maintenance win-

dows and without impacting the performance and availability that customers experience. Software deployments are done for various reasons, including new features, bug fixes, and performance optimizations. Often deployments involve updating numerous services. DynamoDB pushes software updates at a regular cadence. A deployment takes the software from one state to another state. The new software being deployed goes through a full development and test cycle to build confidence in the correctness of the code. Over the years, across multiple deployments, DynamoDB has learned that it's not just the end state and the start state that matter; there could be times when the newly deployed software doesn't work and needs a rollback. The rolled-back state might be different from the initial state of the software. The rollback procedure is often missed in testing and can lead to customer impact. DynamoDB runs a suite of upgrade and downgrade tests at a component level before every deployment. Then, the software is rolled back on purpose and tested by running functional tests. DynamoDB has found this process valuable for catching issues that otherwise would make it hard to rollback if needed.

Deploying software on a single node is quite different from deploying software to multiple nodes. The deployments are not atomic in a distributed system, and, at any given time, there will be software running the old code on some nodes and new code on other parts of the fleet. The additional challenge with distributed deployments is that the new software might introduce a new type of message or change the protocol in a way that old software in the system doesn't understand. DynamoDB handles these kinds of changes with read-write deployments. Read-write deployment is completed as a multi-step process. The first step is to deploy the software to read the new message format or protocol. Once all the nodes can handle the new message, the software is updated to send new messages. New messages are enabled with software deployment as well. Read-write deployments ensure that both types of messages can coexist in the system. Even in the case of rollbacks, the system can understand both old and new messages.

All the deployments are done on a small set of nodes before pushing them to the entire fleet of nodes. The strategy reduces the potential impact of faulty deployments. DynamoDB sets alarm thresholds on availability metrics (mentioned in section 6.3). If error rates or latency exceed the threshold values during deployments, the system triggers automatic rollbacks. Software deployments to storage nodes trigger leader failovers that are designed to avoid any impact to availability. The leader replicas relinquish leadership and hence the group's new leader doesn't have to wait for the old leader's lease to expire.

6.5 Dependencies on external services

To ensure high availability, all the services that DynamoDB depends on in the request path should be more highly available than DynamoDB. Alternatively, DynamoDB should be able to continue to operate even when the services on which it depends are impaired. Examples of services DynamoDB depends on for the request path include AWS Identity and Access Management Services (IAM) [2], and AWS Key Management Service (AWS KMS) [3] for tables encrypted using customer keys. DynamoDB uses IAM and AWS KMS to authenticate every customer request. While these services are highly available, DynamoDB is designed to operate when these services are unavailable without sacrificing any of the security properties that these systems provide.

In the case of IAM and AWS KMS, DynamoDB employs a statically stable design [18], where the overall system keeps working even when a dependency becomes impaired. Perhaps the system doesn't see any updated information that its dependency was supposed to have delivered. However, everything before the dependency became impaired continues to work despite the impaired dependency. DynamoDB caches result from IAM and AWS KMS in the request routers that perform the authentication of every request. DynamoDB periodically refreshes the cached results asynchronously. If IAM or KMS were to become unavailable, the routers will continue to use the cached results for pre-determined extended period. Clients that send operations to request routers that don't have the cached results will see an impact. However, we have seen a minimal impact in practice when AWS KMS or IAM is impaired. Moreover, caches improve response times by removing the need to do an off-box call, which is especially valuable when the system is under high load.

6.6 Metadata availability

One of the most important pieces of metadata the request routers needs is the mapping between a table's primary keys and storage nodes. At launch, DynamoDB stored the metadata in DynamoDB itself. This routing information consisted of all the partitions for a table, the key range of each partition, and the storage nodes hosting the partition. When a router received a request for a table it had not seen before, it downloaded the routing information for the entire table and cached it locally. Since the configuration information about partition replicas rarely changes, the cache hit rate was approximately 99.75 percent. The downside is that caching introduces bimodal behavior. In the case of a cold start where request routers have empty caches, every DynamoDB request would result in a metadata lookup, and so the service had to scale to serve requests at the same rate as DynamoDB. This effect has been observed in practice when new capacity is added to the request router fleet. Occasionally the metadata service traffic would spike up to 75 percent. Thus, introducing new

request routers impacted the performance and could make the system unstable. In addition, an ineffective cache can cause cascading failures to other parts of the system as the source of data falls over from too much direct load [4].

DynamoDB wanted to remove and significantly reduce the reliance on the local cache for request routers and other metadata clients without impacting the latency of the customer requests. When servicing a request, the router needs only information about the partition hosting the key for the request. Therefore, it was wasteful to get the routing information for the entire table, especially for large tables with many partitions. To mitigate against metadata scaling and availability risks in a cost-effective fashion, DynamoDB built an in-memory distributed datastore called *MemDS*. MemDS stores all the metadata in memory and replicates it across the MemDS fleet. MemDS scales horizontally to handle the entire incoming request rate of DynamoDB. The data is highly compressed. The MemDS process on a node encapsulates a Perkle data structure, a hybrid of a Patricia tree [17] and a Merkle tree. The Perkle tree allows keys and associated values to be inserted for subsequent lookup using the full key or a key prefix. Additionally, as keys are stored in sorted order, range queries such as *lessThan*, *greaterThan*, and *between* are also supported. The MemDS Perkle tree additionally supports two special lookup operations: *floor* and *ceiling*. The *floor* operation accepts a key and returns a stored entry from the Perkle whose key is less than or equal to the given key. The *ceiling* operation is similar but returns the entry whose key is greater than or equal to the given key.

A new partition map cache was deployed on each request router host to avoid the bi-modality of the original request router caches. In the new cache, a cache hit also results in an asynchronous call to MemDS to refresh the cache. Thus, the new cache ensures the MemDS fleet is always serving a constant volume of traffic regardless of cache hit ratio. The constant traffic to the MemDS fleet increases the load on the metadata fleet compared to the conventional caches where the traffic to the backend is determined by cache hit ratio, but prevents cascading failures to other parts of the system when the caches become ineffective.

DynamoDB storage nodes are the authoritative source of partition membership data. Partition membership updates are pushed from storage nodes to MemDS. Each partition membership update is propagated to all MemDS nodes. If the partition membership provided by MemDS is stale, then the incorrectly contacted storage node either responds with the latest membership if known or responds with an error code that triggers another MemDS lookup by the request router.

7 Micro benchmarks

To show that scale doesn't affect the latencies observed by applications, we ran YCSB [8] workloads of types A (50 percent reads and 50 percent updates) and B (95 percent reads

Figure 5: Summary of YCSB read latencies

Figure 6: Summary of YCSB write latencies

and 5 percent updates). Both benchmarks used a uniform key distribution and items of size 900 bytes. The workloads were run against production DynamoDB in the North Virginia region. The workloads were scaled from 100 thousand total operations per second to 1 million total operations per second. Figure 5 shows the read latencies of both workloads at 50th and 99th percentiles. The purpose of the graph is to show, even at different throughput, DynamoDB read latencies show very little variance and remain identical even as the throughput of the workload is increased. The read throughput of the Workload B is twice that Workload A and still the latencies show very little variance. Figure 6 shows the writes latencies of both workloads at 50th and 99th percentiles. Like the read latencies, the write latencies remain constant no matter the throughput of the workload. In case of YCSB, workload A drives a higher throughput than workload B, but the write latency profile for both workloads are similar.

8 Conclusion

DynamoDB has pioneered the space of cloud-native NoSQL databases. It is a critical component of thousands of applica-

tions used daily for shopping, food, transportation, banking, entertainment, and so much more. Developers rely on its ability to scale data workloads while providing steady performance, high availability, and low operational complexity. For more than 10 years, DynamoDB has maintained these key properties and extended its appeal to application developers with game-changing features such as on-demand capacity, point-in-time backup and restore, multi-Region replication, and atomic transactions.

9 Acknowledgements

DynamoDB has benefited greatly from its customers whose continuous feedback pushed us to innovate on their behalf. We have been lucky to have an amazing team working with us on this journey. We thank Shawn Bice, Rande Blackman, Marc Brooker, Lewis Bruck, Andrew Certain, Raju Gulabani, James Hamilton, Long Huang, Yossi Levanoni, David Lutz, Maximiliano Maccanti, Rama Pokkunuri, Tony Petrossian, Jim Scharf, Khawaja Shams, Stefano Stefani, Allan Vermuellen, Wei Xiao and the entire DynamoDB team for the impactful contributions during the course of this evolution. Many people have helped to improve this paper. We thank the anonymous reviewers who helped shape the paper. Special thanks to Darcy Jayne, Kiran Reddy, and Andy Warfield for going above and beyond to help.
